Related observations from the JT-60U tokamak (Shinohara et al., 2001) were obtained from experiments with high energy neutral beams injected into plasma (0.36 MeV) in which the velocity of the EP component was near the Alfvén speed, $v_j/v_A \sim 1$. Several instabilities differing in time evolution and frequency were observed. A specific instability was identified as an abrupt large amplitude event (ALE), and this appeared at the end of the fast frequency sweeping (FS as referred to by the authors) instability. FS had a characteristic frequency chirp over the range 10 – 20 kHz with a duration of several milliseconds and was often characterized by a drop in neutron emission, as well as by losses of fast ions from the plasma.

All but one explosive nonlinear scenarios of wave-particle interaction predicted by the Berk-Breizman model were validated experimentally in JET tokamak plasmas. In specific JET experiments, TAEs were excited by energetic hydrogen-minority tail ions accelerated by ICRH. The unstable distribution of energetic ions in this case was replenished by the RF-induced diffusion of the energetic ions, which exceeded the diffusion due to Coulomb collisions by an order of magnitude. Fig. 9 top shows how the gradually increasing ICRH power and associated net growth rate of the TAEs caused the modes to go through the sequence of nonlinear saturated scenarios displayed in Fig. 9 bottom. These scenarios replicate the states shown in Fig. 7.

Firstly, a steady-state nonlinearly saturated amplitude of each mode that corresponds to Fig. 7A is seen in the spectrogram as a single line. This is followed by the nonlinear scenario with a periodic modulation of TAE amplitude (Fig. 7B) that gives a “pitchfork splitting” effect in the spectrogram with several parallel sidebands separated by the frequency of the modulation. Subsequently, the amplitude modulation becomes deep enough for the mode amplitude to cycle close to zero, thus corresponding to Fig. 7C. Finally, when the modulation becomes comparable to the amplitude itself, the chaotic scenario of the mode emerges with non-periodic amplitude variations (see Fig. 7D) and the phase flips near zero amplitude. This chaotic scenario is seen in the spectrogram at late times as a noisy band of frequency width similar to that of the pitchfork-split TAE.

An explosive nonlinear scenario corresponding to Fig. 7E is rather difficult to achieve with ICRH-driven TAEs, which are dominated by the RF-induced diffusion at the resonance due to strong, RF-driven, pitch angle scattering of the EPs. Such a scenario can be produced more easily for TAEs driven by NBI-produced energetic ions, where replenishment of the EP distribution function around the resonance condition is dominated by slowing down from the EP injection energy and Coulomb scattering is much weaker.

Reduced analytic and quasi-linear models

Due to the larger size and cost of future burning plasma experiments it is increasingly important to develop reduced models capable of predicting reliable scenarios for AE excitation and evolution in both present day and future experiments. Several models exist with such capabilities, for both single-mode and multi-mode cases. They include simple critical gradient models (Ghantous

Fig. 9 Top: the wave-forms of ICRH and NBI auxiliary heating power in JET discharge #49447. Bottom: Amplitude spectrogram of magnetic fluctuations showing the various non-linear scenarios of TAE evolution. The TAEs have toroidal mode numbers $n = 3$ to 6.

et al., 2012; Bass and Waltz, 2020), which describe the relaxation of the EP plasma component without resolving the velocity distribution function. More sophisticated models include the quasi-linear (QL) simulations which incorporate the phase velocity diffusion by resolving the wave-particle resonances, their overlaps and particle dynamics near the resonances (Ghantous et al., 2014; Gorelenkov et al., 2019).

The reduced models are developed with the goal of being predictive for efficient WDM simulations. Depending on the efficiency of the models they can be used for different purposes within the simulations, yielding less (simple models without resolution of details of the distribution function) or more (more sophisticated, quasi-linear models) reliable predictions. Because of their demands, WDM require significant investment in terms of verification and validation. Nevertheless, the benefits for fusion research are substantial, since the required computational resources are significantly lower and yet the models are accurate enough to predict such demanding characteristics as the induced current drive.

Reduced analytic models have been developed recently. One particular noteworthy result emerged from simplification of the cubic equation (14) in the limit when the resonant particle dynamics can be described by the dominant pitch angle scattering only. This allowed derivation of the AE amplitude in a form which is relatively easy to evaluate:

$$A(t) = A(0) \frac{e^t}{\sqrt{1 - gA^2(0)(1 - e^{2t})}}; g \equiv \int d\Gamma H \frac{\Gamma(1/3)}{6\nu_{\text{eff}}^4} \left(\frac{3}{2}\right)^{1/3}, \quad (15)$$

where g is the resonance-averaged effective pitch angle scattering contribution and H is the phase space weighting (Duarte et al., 2019).

It is also noteworthy that the predictions of the AE amplitude can be performed analytically, which is extremely useful verification for numerical simulations and reduces simulation requirements.

Semi-analytic 1D models for bump-on-tail drive

Important insights into the nonlinear physics can be derived from simple models in which, by reducing the dimensionality of the problem, it is possible to focus on the underlying physics. Several 1D models (Vann et al., 2003; Lilley et al., 2010, and Lesur et al., 2009) were developed with the aim of capturing the important features of the wave-particle resonant interaction.

Vann et al. (2003) proposed a Vlasov (1968) approach to finding the EP distribution function in order to numerically characterize the nonlinear behavior in a marginally unstable dissipative system by accurately computing the wave particle interaction near each resonance in velocity space. A somewhat simpler approach by Lilley et al. (2010) addressed single resonance dynamics and elucidated the relative roles played by various collision effects, such as pitch angle scattering and velocity slowing down,

Krook-like relaxation and phase-space diffusion. The model was capable of including several additional important elements, such as the slowing down process (drag), which is destabilizing for energetic particle modes. The model also generated asymmetries in the evolution of the frequency chirps. Another group led by Lesur and Idomura (2012) independently developed a 1D electrostatic code and defined a qualitative definition for each of the chirping regimes with drag and diffusion. These nonlinear 1D models show that mode behavior close to marginal stability is well characterized both theoretically (Berk et al., 1996) and experimentally using simple parameters and can even provide opportunities to extract additional information on the particle phase space distribution from the measured instability spectral features (Fasoli et al., 1998).

Models for initial value simulations

There are two widely used codes which are unique in treating the wave-particle phenomena found in experiments. These codes, which treat the influence of the energetic particles perturbatively upon the linear eigenfunctions of the system, are ORBIT (White and Chance, 1984) and HAGIS (Pinches et al., 1998). These models have been used successfully to describe the fully nonlinear interaction of fast ions with the linear waves in the plasmas and have even shown how it is possible to recover the internal amplitude of a mode from observations of its frequency chirps (Pinches et al., 1998). ORBIT was able to successfully simulate AE chirping in the NSTX device and to predict the AE avalanche onset by slightly increasing (by 10%) the growth rate of the unstable modes from the values computed prior to the avalanche.

Going beyond the linear MHD eigenmode structures, as required for lower-frequency BAE modes, necessitates formulation of a model based on a nonlinear MHD approach. This is the method adopted in the MEGA code (Todo and Sato, 1998), which is a kinetic-MHD hybrid model that has been used to simulate the interaction of alpha particles with various Alfvén eigenmodes. The plasma is divided into two species: the background plasma and the energetic particles. The behavior of the energetic ions is coupled to the MHD equations through the current that they carry. A linearized version of the code also exists to facilitate understanding of the nonlinear behavior observed.

Another code that can capture the non-perturbative effects of energetic particles is the HMGC code (Briguglio et al., 1995). This is a hybrid MHD-particle simulation code that couples the sets of reduced MHD equations for the fluctuating fields with the gyrokinetic equations of motion for the fast ions. At each time step the particles move in the 3D electromagnetic field before the field is updated using a fluid-equation solver.

The above approaches use the kinetic treatment for the energetic particle behavior. However, it is also possible to take a gyro fluid-based approach, as done by the TAEFL code (Spong et al., 2012). This allows the study of TAEs destabilized by fast ions while still capturing the mode damping due to neighboring shear Alfvén continua. Recent work (Spong et al., 2012) has shown good qualitative agreement between this approach, experimental observations in a DIII-D discharge and the results of two gyrokinetic codes, GTC (Lin et al., 1998) and GYRO (Candy and Waltz, 2003), both for the mode evolution (frequency sweeping) and mode structure.

Implications for burning plasmas

One of the main uncertainties in predicting with confidence a burning plasma performance is a possible excitation of multiple Alfvénic instabilities (Fasoli et al., 2007; Gorelenkov et al., 2014). If the amplitudes of these instabilities are not benign, a transport of fast ions exceeding the neoclassical values can arise giving a radial re-distribution of the fast ions, affecting the power deposition profile and endangering the integrity of the first wall.

The fast ions in ITER will consist of fusion-born alpha-particles, ICRH-accelerated ions, and 1 MeV deuterium beam ions. In addition to the alpha-particles, the D-beam ions injected tangentially into ITER plasmas, will also have a destabilizing effect on TAEs. Due to the anisotropic distribution function of the beam, the beam drive of AEs can be comparable to the alpha-particle drive (Gorelenkov et al., 2005), implying that the beam-driven Alfvénic instabilities should be carefully assessed as an addition to alpha-driven instabilities, in particular by following the plasma simulation along the entire transport path that uses NBI toward achievement of the $Q = 10$ operation point.

The relaxation of the fast ion distribution caused by the modes depends on whether the wave-particle resonances overlap and can induce a stochastic transport of the fast ion orbits across a significant radial distance. The stochasticity condition depends primarily on the position of wave-particle resonances in the phase space, on the number of unstable modes, their toroidal mode numbers and the maximum amplitudes they reach. It also depends on whether the instabilities are in stationary regimes, where their frequencies and amplitudes are not changing much in time, or they are in the frequency chirping and amplitude bursting regime associated with the structures in the fast ion phase space (White et al., 2020) as described in section “Nonlinear evolution of EP-driven modes and energetic particle transport.”

For the linear AE instability the dominant dependence on the mode number comes from the finite orbit width effect (Fu and Cheng, 1992; Breizman and Sharapov, 1995), which can be cast into the condition that the radial width of the mode eigenstructure is comparable to the radial width of the EP drift orbit for maximizing the mode growth rate,

$$k_{\perp} \rho_f \sim 1, \quad (16)$$

where ρ_f is the Larmor radius of the fast (beam or alpha) ion.

This condition is important, especially for AE stability analysis in ITER. It allows an approximate evaluation of the most unstable AE mode number and the range of unstable modes.

As the linear AE theory is well developed, an important further step is the validation and verification of various linear and nonlinear TAE stability codes. An international benchmarking exercise has therefore been performed over several years under the auspices of the Energetic Particles (EP) Topical Group of the International Tokamak Physics Activity (ITPA, <http://www.iter.org/org/team/fst/itpa>). The overall aim of this exercise was, for each numerical simulation code, to verify the code's implementation and to validate its predictive capability for ITER.

Here we present a table of TFTR and JET energetic particle parameters achieved to date together with the predicted EP parameters in ITER. The most critical parameters for energetic ion studies are presented, such as their local gradient values $|R\nabla\beta_f|$, ratio to the Alfvén speed, EP density and pressure, which are important for evaluating the AE stability in the referenced tokamaks.

AE linear growth and damping rates

A comprehensive description of Alfvénic instabilities excited by energetic particles requires a development of numerical tools accurately computing, for a given equilibrium, the spectrum of Alfvén eigenmodes (AEs) and the energetic particle orbits. Historically, different approaches were used for describing both AEs and the orbits, and the numerical tools developed were validated against experimental data from the range of experimental devices. In order to assess with confidence the strong and weak sides of the codes developed, an international benchmarking exercise was implemented under the auspices of the Energetic Particles Topical Group of the International Tokamak Physics Activity (ITPA, <http://www.iter.org/org/team/fst/itpa>) to verify various implementations and to validate the codes' behavior for ITER.

The code benchmarking exercise centered around the application of each code to a specific, well-documented JET plasma (Borba et al., 2010; Testa et al., 2010) in which the damping of global TAEs was measured, or the codes were run for the analytic case (Könies et al., 2018). The models employed included the perturbative kinetic extension to MHD codes, CASTOR-K (Huysmans et al., 1993) and NOVA-K (Gorelenkov et al., 1999), warm dielectric tensor model code LEMan (Popovich et al., 2006), gyro fluid code TAEFL (Spong et al., 1994) and linear gyrokinetic code LIGKA (Lauber and Günter, 2008). Most importantly, the damping rate of a specific TAE mode was measured with the active TAE-antenna diagnostics, so that this activity validated the codes against experimental data.

The codes used found two TAE modes with $n = 3$ and radially extended mode structures. One of these, a Global TAE mode, was identified as a likely candidate corresponding to the measured TAE damping rate, because it had the eigenfrequency $f = 179 - 181$ kHz which did not cross the Alfvén continuum. The computed TAE structures allowed the interaction with the continuum at the edge and near the center. Computed damping rates gave a good agreement with the experiment for the $n = 3$ TAE for the codes using different approaches, see Fig. 10. Analysis shows that the computed rates consist of primarily two dominant mechanisms: the continuum and the radiative damping effects.

More recently, results have been obtained from a further significant code cross-verification focusing on the growth rate calculations by many codes, once again in the linear regimes. These codes use somewhat different and independent approaches to compute the fast ion growth rates and included CAS3D-K (Könies et al., 2008), GYGLES (Mishchenko et al., 2009), TAEFL (Spong et al., 1994), AE3D-K (Spong et al., 2010), NOVA-K (Gorelenkov et al., 1999), HMGC (Briguglio et al., 1995), MEGA (Todo and Sato, 1998),

Fig. 10 The figure shows damping rates for TAE modes calculated by the computational codes indicated as a function of time and the comparison with the JET experimentally inferred damping rate.

Fig. 11 Predictions for the $n = 6$ TAE growth rate, γ , as a function of the energetic particle ‘temperature’ (assuming a Maxwellian distribution for the energetic particles), T_i , derived from a range of codes using an analytic formulation of the plasma profiles (the comparison was performed within the framework of an ITPA benchmarking activity).

CKA-EUTERPE (Kleiber, 2006), VENUS (Cooper et al., 2011). Fig. 11 represents the growth rates resulting from these nine codes whose models range from the kinetic MHD/hybrid to gyro-kinetic and gyro-fluid approaches.

To simplify the comparison among the codes, analytic plasma profiles were chosen with a large aspect ratio $R/a = 10/1$ and a q -profile that allowed the growth of only one TAE couplet (m and $m + 1$ poloidal harmonics). Within a reasonable error range, indicated as a shaded region in Fig. 11, the code predictions are in agreement. They all reflect the existence of a plateau in the growth rate dependence as a function of the fast ion temperature, which is an important result underpinning burning plasma projections. For this analysis, the EP distribution function was taken to be a Maxwellian to allow ease of comparison among the code calculations. The growth rates shown include the finite orbit width effect but neglect the finite Larmor radius effect (i.e., zero Larmor radius is assumed). The agreement among the codes is satisfactory in terms of the growth rate vs ion temperature, within $\sim 15\%$ for energies up to the plateau point at ~ 400 keV.

Alfvén wave excitation in ITER baseline scenario

Predictive studies of both the linear and nonlinear behavior of Alfvénic instabilities in ITER plasma scenarios are a key priority for exploitation of the various numerical codes applied in the benchmarking exercise described in section “Alfvén wave excitation in ITER baseline scenario.” An important requirement for such predictions is the credibility in the representation of the dominant damping mechanisms and accurate calculations of the growth rates. The damping rates should include most of the known mechanisms, namely, electron and ion Landau damping, collisional electron damping and radiative/continuum damping. The fusion alpha-particle drive should include both the finite orbit width (FOW) and finite Larmor radius (FLR) effects, which are important to correctly represent the range of unstable AE growth rates and how they saturate at the maximum value, as defined by Eq. (16). The dominant drive of AE instabilities is generated by alpha-particles resulting from DT reactions, but other ions could also contribute, as pointed out in the introduction to this sub-section.

An important example of possible alpha-particle driven TAEs (Fasoli et al., 2007) is the case of an ITER baseline scenario with 15 MA current at the $Q = 10$ operational point. The main plasma parameters were predicted with the ASTRA transport code (Polevoi et al., 2002). In this scenario, the alpha-particle density is moderately high, with a normalized alpha-particle pressure on the plasma axis, $\beta_\alpha(0) \approx 1.2\%$, and with the maximum radial gradient at about $r/a \leq 0.4$ (Pinches et al., 2015). The predicted plasma profiles for this scenario are illustrated in Fig. 12.

This plasma has sawteeth, which make the safety factor profile $q(r)$ very flat in the central region of $r/a \leq 0.5$, with $q(0) \leq 1$. For flat $q(r)$ -profiles, TAE-gaps in the Alfvén continuum localized at

Fig. 12 Plasma profiles predicted with the ASTRA transport code (Polevoi et al., 2002) for ITER baseline scenario with current $I_p = 15\text{MA}$, $R = 621 \text{ cm}$, $a = 200 \text{ cm}$, and $B_T = 5.3 \text{ T}$ (Pinches et al., 2015). Left: density of electrons, D-T ion mixture (50:50), and He ash. Right: temperature of thermal ions and electrons.

$$q_{TAE} = \frac{m + 1/2}{n}, \quad (17)$$

become sparse in the core region of $r/a \leq 0.4$, where the maximum radial gradient of alpha-particles occurs. The existence of a TAE-gap is a necessary condition for the existence of a TAE-mode. Hence, the very low density of the TAE-gaps in the central plasma region indicates that this region has very few TAE-modes. Moreover, in this central region, the very few number of TAEs also have quite narrow radial mode width. If excited, such modes can only flatten the alpha-particle profile over a limited region corresponding to the radial mode width. In the area of larger magnetic shear, $r/a \geq 0.5$, the density of TAE-gaps increases significantly, so that the distance between the gaps becomes less than the width of the gaps. Global TAEs are formed in this case which are capable of transporting resonant alpha-particles over a significant radial distance. However, these TAEs are localized in the region, i.e., close to the plasma edge, with a smaller population of alpha-particles. The global character of such TAEs is therefore counter-balanced by a lower alpha-particle drive and a lower alpha-particle density.

Numerical modeling of TAEs

In order to assess both global linear stability of TAEs and nonlinear TAE evolution, all TAEs (there are 129 eigenmodes) with toroidal mode numbers $1 \leq n \leq 35$ were computed with the spectral MHD code MISHKA (Mikhailovskii et al., 1997). Among these modes, core-localized TAEs of both even and odd parity (i.e., with the same or opposite signs of the poloidal harmonics m and $m + 1$) were found, and a significant number of global TAEs were also identified. The linear alpha-particle drive was computed with the HAGIS code (Pinches et al., 1998) for every individual TAE, as shown in Fig. 13 (left). The damping of every TAE was then assessed with the CASTOR-K code (Borba et al., 2002), with the dominant damping being the thermal ion Landau resonance. The non-linear evolution of all TAEs with damping effects included, and interacting with the same alpha-particle population, was then computed with the HAGIS code. 2D contours of the saturated TAE amplitude are shown in Fig. 13 (right). It was found that TAEs reach amplitudes approaching $\delta B_r/B \approx 3 \times 10^{-4}$, with the core localized TAEs being the largest (Fitzgerald et al., 2016).

Fig. 13 Left: Linear growth rates for TAE modes in ITER computed by the HAGIS code (Pinches et al., 1998) by fitting to the first 20 wave periods in the absence of damping or coupling. The even parity core localized modes (black star) have higher growth rates than the odd parity core (blue triangle) and high shear TAEs (red circle). Right: 2D plot of computed saturated TAEs in the ITER baseline scenario (Fasoli et al., 2007). Here, non-linear saturation was computed of 129 TAEs with $n = 1-35$, including alpha particle drive, thermal plasma Landau damping, and radiative damping.

Prediction of a similarly low TAE saturation amplitude, i.e., $\delta B_r/B \sim 10^{-4}$, was independently obtained by (Schneller et al., 2016), where it was found that inclusion of Landau damping was essential to predicting the low saturation amplitude and the resultant small alpha-particle transport. Otherwise, nonlinear cascade effects were significantly exaggerated in the simulations.

At the low saturation levels derived from the simulations, radial transport of alpha-particles is limited to several centimeters near the location of the core localized modes. It should be emphasized, however, that the limited alpha-particle transport due to TAEs is partially due to the separation between core and edge TAEs, and that the analysis may be not so optimistic for plasmas with higher magnetic shear. Finally, the super-Alfvénic neutral beams and the potential error bar in damping predictions imply that some caution should be exercised in ruling out global alpha-particle redistribution in this scenario. Nevertheless, further simulations using the HAGIS code showed that global stochasticity effects, which produce large radial transport, only occur if the TAE amplitudes in Fig. 13 (right) increase by a factor of ~ 50 over the computed saturation levels (Fitzgerald et al., 2016). With such a significant enhancement factor required for global stochasticity, one could expect with confidence that TAEs will not cause a significant alpha-particle transport in the specific case of the ITER Q = 10 baseline scenario.

Both simulations acknowledge that the effect of Coulomb scattering plays a rather small role in AE driven relaxation of fast ions.

Glossary

Alfvén velocity The group and phase velocities associated to Alfvén waves are of the order of the Alfvén velocity, $v_a \equiv B_0 / (\mu_0 n_i m_i)^{1/2}$, with B_0 the confining magnetic field, μ_0 the vacuum permeability and n_i (resp. m_i) the ion density (resp. mass). This ratio reflects the antagonistic effects of the magnetic field line tension on the one hand, and of the ion inertia on the other hand.

Alfvén waves A kind of magnetohydrodynamic wave characterized by a periodic oscillation of the plasma ion drift motion associated to a perturbation of the magnetic field. It is characterized by a frequency much lower than the ion cyclotron frequency. Alfvén waves play an important role in magnetic fusion plasmas because they can interact efficiently with energetic ions and, in some situations, induce a radial displacement of these particles (Gorelenkov and Sharapov, 2021).

Boltzmann equation A kinetic equation describing statistical properties of a thermodynamic system out-of-equilibrium. In practice, the generic form of the collision term appearing in this equation prevents it from being directly applied to fully ionized plasmas in which long-range Coulomb collisions dominate.

Bootstrap current A contribution to the toroidal plasma current resulting from the fact that the plasma pressure is maximal near the plasma center and decreases towards the edge. Because of this non-uniformity, the friction between trapped electrons and passing electrons results in a net transfer of parallel momentum from the former to the latter, inducing a finite parallel current (Helander and Sigmar, 2005). In tokamaks, the (beneficial) bootstrap contribution to the total current can be quite significant (typically $\sim 50\%$ in ITER, depending on the regime of operation).

Coulomb logarithm This quantity appears in the theory of Coulomb collisions taking place between the charged particles comprising a plasma. Denoting Λ the approximate number of particles contained in the Debye sphere, its logarithm, $\ln(\Lambda)$, is much larger than unity in weakly coupled plasmas, in which collective effects dominate (Goldston and Rutherford, 1995). Fusion plasmas are examples of weakly coupled plasmas and it is found that $\ln(\Lambda)$ ranges from ~ 17 (current fusion experiments) to ~ 18 (fusion reactors).

Fokker-Planck equation An equation deduced from the Boltzmann equation assuming that long-range collisions dominate, as is appropriate in hot magnetic fusion plasmas. The ensuing accumulation of multiple small angle deviations for a given particle results in a diffusion equation for the distribution function in velocity space.

keV In magnetic fusion plasmas, it is customary to express energies in terms of electronvolt (eV), kilo-electronvolt (keV) or mega-electronvolt (MeV). 1 eV is approximately equivalent to 1.602176×10^{-19} J. By extension, this unit is also employed for plasma temperatures: 1 eV is approximately equivalent to 1.160450×10^4 Kelvin.

Quasilinear equation A kinetic equation describing the secular (i.e. long duration) effect of the interactions taking place between an electromagnetic wave and the plasma particles. It is obtained by averaging the Vlasov equation over a time much longer than the wave period, and over a space region with a large extension compared to the wavelength.

Trapped/passing particles In a magnetic confinement device, the confining magnetic field B_0 is non-uniform. The velocity vector, $\mathbf{v}$, of a given particle of mass, m , can be written in terms of parallel ($v_{\parallel}$) and perpendicular ($v_{\perp}$) components with respect to the magnetic field direction. Magnetic confinement imposes that the particle kinetic energy, $E = m(v_{\parallel}^2 + v_{\perp}^2)/2$, and its magnetic moment, $\mu = mv_{\perp}^2/(2B_0)$, be conserved to lowest order. By manipulation of these two equations, it can be demonstrated that particles can be classified into two main categories: some are characterized by trajectories with $v_{\parallel} \neq 0$ at any point, whereas others periodically see their parallel velocity cancel. The former are passing particles, and perform complete toroidal revolutions. The latter, on the other hand, travel back and forth in the toroidal direction and are called trapped particles. In particular, trapped electrons do not carry any toroidal current.

Vlasov equation A kinetic equation obtained by neglecting inter-particle correlations in the kinetic description of the plasma, i.e. assuming that all particle interactions are mediated by a self-consistent average electromagnetic field satisfying Maxwell's equations. Since collisions are neglected in this process, this equation is applicable to timescales much smaller than the typical collision time. It is sometimes referred to as the collisionless Boltzmann equation.

WKB (Wentzel-Kramers-Brillouin) approximation A special case of multiple scale analysis. In the context of waves propagating in plasmas, it is relevant when the plasma varies on a space scale much larger than the wavelength. In this case, at a given position x , the electromagnetic field can be written in the form of $E(x) = E_0(x)\exp(iS(x))$, where $E_0(x)$ is assumed to vary slowly compared to the phase $S(x)$. It is applicable outside of wave cut-offs or resonances (Swanson, 2003).

Introduction

The principle of heating and current drive of magnetic confinement fusion plasmas consists of transferring energy produced by a power source to the plasma species. Whereas heating results in an increase of their temperature, more sophisticated schemes, among which current drive, are used as a means to control the plasma and ensure its state remains optimal with respect to fusion power production. In present day devices, the electrical grid typically supplies this power. On the other hand, the burning plasmas contained in future reactors will essentially be self-sufficient in terms of power: one fifth of the energy produced by the D-T reactions comes in the form of kinetic energy of ^4He (alpha) particles, which is much larger than the average energy of any other species present in the plasma. Upon collisional slowing-down on the background species, the alpha particles will yield their energy to the plasma. A fraction of the fusion power produced in-situ will also be recirculated to feed external generators used mainly for plasma control. These considerations apply to the two main classes of reactors envisaged today, i.e. tokamaks (Zohm, 2021) and stellarators (Yamada, 2021). In modern fusion installations, there exist two main classes of external power sources: (1) radio-frequency systems, (2) neutral beam injection systems.

Every radiofrequency (RF)-based heating and current drive method relies on an external power source on the one hand and an adapted antenna located near the plasma edge on the other hand. How this power travels between the source and the antenna depends on the frequency range. In an optical-like description of the process, in all cases, an electromagnetic wave eventually leaves the antenna and propagates to the plasma core where it is absorbed by the plasma species by two main non-collisional mechanisms: Landau damping and cyclotron damping. These mechanisms result in the direct damping of the wave power by one or several thermal species that will be heated as a result, and/or the creation of energetic particle populations (i.e. particles with typical energies much larger than the thermal energy characterizing the background plasma species) which eventually heat the plasma by collisional relaxation.

Neutral beam injection (NBI) consists of producing high-energy ions in an external accelerator and neutralizing them at the end of the acceleration process. These neutral particles, being immune to the effects of the magnetic trap in which the thermal species are confined, can penetrate deep in the plasma. In this process, the vast majority of the energetic particles are re-ionized. Since the re-ionization occurs when the injected particle energy is much larger than that of the thermal species, the result is a population of energetic ions that eventually slow down through collisions with the background particles, to which they transfer their energy.

Finally, fusion products are usually born at very high energies, the most prominent being the alpha particles from D-T reactions born around 3.5 MeV. The relaxation process is essentially similar to the one taking place for NBI ions, i.e. results in a transfer of the fusion product energy to the background electrons and/or fuel ions and the subsequent heating of the plasma. A plasma can be qualified as “burning” when this self-heating process provides a source sufficient for the fusion reactions to be maintained with little or no input required from auxiliary power sources.

Current drive is essential in tokamaks, which require the presence of a poloidal magnetic field produced by the toroidal plasma current (Wesson, 2011). This current can be induced in the plasma by the central solenoid, part of the poloidal circuit (ohmic current)—an inherently non-stationary process—or self-generated by the plasma pressure gradient (*bootstrap current*). The ohmic and bootstrap currents generally need to be supplemented by additional sources to achieve stationary plasma discharges. Furthermore, current profile control is known to be beneficial in terms of plasma stability and performance (Jenko, 2020), but requires

a level of flexibility only achievable with external current drive sources. Some NBI systems are flexible enough for part of the energy to be injected parallel to the magnetic field, which has the effect of driving toroidal current, albeit with a limited flexibility in terms of current profile control. RF wave systems have also been applied for non-inductive current drive for several decades, and are planned to be used for this application in next-step devices. In stellarators, the magnetic field, including its poloidal components, is entirely generated by the coil system, resulting in more modest requirements in terms of external current drive. Nevertheless, the capability to drive non-inductive current is still desirable to compensate for the self-generated bootstrap current.

A global summary of the process of heating and current drive is shown in Fig. 1.

Kinetic theory elements

Heating and current drive results in modifications of the velocity distribution function, f_s , of a given plasma species, denoted s . From this quantity, it is possible to construct the so-called fluid moments (Sarazin, 2021), which include the density, $n_s = \int d^3v f_s$, the current, $j_s = q_s \int d^3v v f_s$, and the temperature, $T_s = \int d^3v m v^2 f_s / 2$. To lowest order, plasma heating and current drive from external sources results in modifications of these three fluid quantities. Clearly, the knowledge of f_s is therefore the first and most important element of the description of the physics processes involved. Furthermore, the RF wave heating and current drive processes involve wave-particle resonances which are dependent on the particle velocities on an individual basis (as opposed to the fluid velocity, which is a macroscopically averaged quantity). As a result, the kinetic theory is the appropriate framework in which these phenomena must be described.

Fokker-Planck equation

The *Fokker-Planck equation* is the classical tool employed to describe heating and current drive processes (Brambilla, 1998). It is derived from the more generic kinetic *Boltzmann equation* assuming that Coulomb collisions result in multiple small angle deviations for a given particle, a valid assumption in the context of magnetically confined fusion plasmas. Formally, this equation takes the form of an evolution equation for the distribution function, f_s , in velocity space under the effects of collisions, particle source and particle losses:

$$df_s/dt = C(f_s) + S_s - L_s. \quad (1)$$

S_s is the particle source (relevant in the case of NBI and/or fusion-born alphas, in which new particles are permanently injected in the system) and L_s is a loss term describing the particles leaving the system by various mechanisms (orbit losses, charge exchange ...), while $C(f_s)$ represents the effect of collisions, and can be written in the form:

$$C(f_s) = -\nabla_v \cdot (\langle \Delta v \rangle / \tau_c f_s) + 1/2 \cdot \nabla_v \nabla_v \cdot (\langle \Delta v \Delta v \rangle / \tau_c f_s) \quad (2)$$

Fig. 1 Summary of the main heating and current drive sources in modern magnetically confined fusion plasmas.

τ_c is a collision time. ∇_v is a differential operator with respect to components of the velocity, $\mathbf{v}$. In Eq. (2), the first term represents a convection process, whereas the second term represents a random walk. The Fokker-Planck equation therefore describes a convection-diffusion process taking place in velocity space. The quantity $F \equiv \langle \Delta \mathbf{v} \rangle / \tau_c$ is called the coefficient of dynamic friction, whereas $D \equiv \langle \Delta \mathbf{v} \Delta \mathbf{v} \rangle / \tau_c$ is the diffusion tensor.

In its generic form—consistent with the assumptions made to obtain the Fokker-Planck equation, F and D involve all species present in the plasma, making C a non-linear operator which can be quite complex to evaluate. It becomes much more tractable when assuming that the background species, i.e. all species but the heated one(s) have Maxwellian velocity distributions, an assumption often legitimate in the context of heating and current drive in magnetic fusion plasmas.

Collisional processes

As described previously, the Fokker-Planck equation (1) describes the collisional processes governing the relaxation of any energetic particle population, and hence the energy transfers taking place between this population and the background plasma species (Goldston and Rutherford, 1995). This equation can be solved efficiently on any modern computer using various numerical methods, typically in a Monte Carlo form, or using finite differences/elements. However, much insight into the relaxation process itself can be gained by examining the relaxation of a single test ion on the background plasma species, which are assumed fixed. From the coefficients $\langle \Delta \mathbf{v} \rangle$ and $\langle \Delta \mathbf{v} \Delta \mathbf{v} \rangle$ derived to construct the collisional term (Eq. 2), trajectories in velocity space of an ion with charge number, Z_f , and mass number, A_f , injected (or born) at a given velocity, V_f , and undergoing the influence of Coulomb collisions can be computed.

In the range of energies relevant to energetic ions (NBI or fusion-born), V_f always satisfies $v_{th,i} \ll V_f \ll v_{th,e}$, with $v_{th,i}^2 \equiv 2k_B T_i / m_i$ and $v_{th,e}^2 \equiv 2k_B T_e / m_e$ the (squared) thermal velocities of background ions (of mass m_i) and electrons (of mass m_e). T_e and T_i are the corresponding temperatures and k_B is the Boltzmann constant. Using this assumption, the dominant collisional processes are found to be (1) a decrease of the test ion velocity resulting from the collisional friction against the background species; (2) a scattering of the test ion pitch-angle (relative to the magnetic field), i.e. a modification of the direction of its velocity with respect to its initial velocity.

A closer examination of the magnitude of these processes allows three important quantities to be identified: (1) the Spitzer slowing-down time (in seconds), $\tau_{se} \equiv 6.32 \times 10^{14} (A_f / Z_f^2) (T_e^{3/2} / n_e) \ln(\Lambda)$, with $\ln(\Lambda)$ the *Coulomb logarithm* and T_e (resp. n_e) the background electron temperature in eV (resp. density in m^{-3}); (2) the critical energy, $E_c \equiv 14.8 (Z_i^2 / A_i) A_f T_e$, with A_i and Z_i the background ion mass and charge number; (3) the thermalization time, $\tau_{th} \equiv \tau_{se} \ln(1 + (E_f / E_c)^{3/2}) / 3$. The Spitzer time describes the rate of change of the test particle velocity caused by the friction on background electrons, i.e. $dv_f/dt = v_f / \tau_{se}$ (i.e. assuming only electrons are involved in the slowing-down process). The critical velocity corresponds to the limit below which pitch-angle scattering and drag by background ions exceeds the scattering and drag caused by electrons. When the test ion reaches E_c , both the background electrons and ions contribute equally to its slowing down. However, the fact that the masses of the test and background ions are not very different also induces significant pitch-angle scattering by the latter. The corresponding decrease in the test particle energy does not result in background plasma heating, but rather in an increased spread in the energetic population velocities. Finally, the thermalization time corresponds to the delay for the test ion to reach the thermal velocities. It should be noted that τ_{th} and τ_{se} can be quite different, as illustrated by the data shown in Table 1.

Quasilinear description of RF heating

The first step towards describing plasma heating by RF waves is to solve the wave equation for the wave electric field, $\mathbf{E}$. The wave magnetic field, $\mathbf{B}$, can always be deduced from $\mathbf{E}$ using Maxwell's equations. Assuming a time-harmonic field varying at an angular frequency, ω (imposed by the generator), i.e. $\mathbf{E} \propto \exp(-i\omega t)$, with t the time, the wave equation is a straightforward consequence of Maxwell's equations, and is written here in the symbolic form:

$$\nabla \times \nabla \times \mathbf{E} - \omega^2 / c^2 (\mathbf{E} + i \mathbf{J}_p / \omega \epsilon_0) = i \omega \mu_0 \mathbf{J}_{ant}. \quad (3)$$

In this expression, ∇ is a differential operator (in real space), μ_0 is the vacuum permeability, ϵ_0 the vacuum permittivity, and c is the speed of light. $\mathbf{J}_{ant}$ represents the boundary condition imposed by the antenna. Despite its apparent simplicity, this equation is quite complicated because the response plasma current, $\mathbf{J}_p = \mathbf{J}_p(\mathbf{E})$, has a complex, temporally and spatially non-local, dependence

Table 1 Main parameters relevant to the collisional relaxation of NBI ions in JET D, JET DT, ITER D, and ITER DT plasmas.

Background plasma/test particle	Initial energy (keV)	Critical energy (keV)	Spitzer time (s)	Thermalization time (s)	Fraction of power to ions/electrons
JET D/D NBI	100	187	1.45	0.16	0.87/0.13
JET DT/DT NBI	100	206	1.81	0.18	0.89/0.11
ITER D/D NBI	1000	466	2.64	1.25	0.53/0.47
ITER DT/D NBI	1000	413	2.64	1.34	0.50/0.50

on the wave electromagnetic field. A first simplification occurs assuming that this dependence is linear, a hypothesis generally valid in the context of plasma heating and current drive, where the electromagnetic field is a perturbation for the magnetically confined plasma.

Another source of difficulty related to Eq. (3) is the fact that J_p depends itself on the distribution function of the various plasma species, including the species which directly absorb the injected power. In other words, it is often necessary to solve the wave equation and an equation to describe the modification of the distribution function in a self-consistent fashion. This two-step approach relies on the fact that the timescales related to the wave propagation and damping are small compared to the timescales related to the secular modifications of the distribution function and Coulomb collisions, which correspond to the macroscopic modifications of the plasma caused by the wave power.

Including RF wave effects on the distribution function requires additional assumptions with respect to those made to derive the Fokker-Planck equation (Eq. 1). The *quasilinear equation* is obtained from the *Vlasov equation* assuming that the non-linear effect of the wave on the distribution function is the product of interactions taking place between the wave field, as deduced from the linearized wave equation (Eq. 3) on the one hand, and of the linear plasma response on the other hand, hence the name quasilinear. This procedure requires an averaging over space (resp. time) scales larger than the wavelength, λ (resp. wave period τ), to eliminate all terms varying on the small space scale, λ , and fast time scale, τ . This quasilinear equation—customarily also referred to as Fokker-Planck equation—therefore applies to F_s , the time and space-averaged version of f_s . Following this procedure, it can be written in the form:

$$dF_s/dt = C(F_s) + Q(F_s) + S_s - L_s. \quad (4)$$

Q is the quasilinear operator, and represents the effect of the waves interacting with the particles of species s on the corresponding distribution function, F_s . In the framework of the quasilinear theory, this term also takes the form of diffusion/friction term involving a quasilinear diffusion tensor, D_{ql} :

$$Q(F_s) = \nabla_v \cdot (D_{ql} \cdot \nabla_v F_s) \quad (5)$$

Depending on the level of sophistication of the description used, Q can have a rather complicated form. Important features of the quasilinear operator can nevertheless be isolated by writing any of its components in the symbolic form:

$$D_{ql} = A \sum_p \left| d^{(p)}(E) \right|^2 \delta(\omega - p\Omega_{cs} - k_{||}v_{||}) \quad (6)$$

In this expression, A is a constant. $d^{(p)}(E)$ is a differential operator acting on the electromagnetic field and $k_{||}$ is the projection of the wave vector in the direction parallel to the magnetic field lines. These two elements are essentially representative of the wave field. $\Omega_{cs} = q_s B_0 / m_s$ is the (algebraic) cyclotron frequency, i.e. the frequency of the cyclotron motion of the considered particles (with charge, q_s , and mass, m_s) around the magnetic field line. Ω_{cs} and $v_{||}$, the particle velocity along the field line, are characteristics of the interacting particles trajectories. p , the harmonic number, is an integer which can have either sign, or be 0. $\delta(\omega - p\Omega_{cs} - k_{||}v_{||})$ is non-zero only when the particles are resonant with the wave, i.e. when the wave-particle resonance condition, $\omega = p\Omega_{cs} + k_{||}v_{||}$, is satisfied.

RF wave propagation and damping

In RF heating processes, generators located at some distance from the plasma confinement device generate oscillating currents. Depending on the frequency range, the corresponding power is transported to an antenna located inside the vacuum vessel, usually close to the plasma edge (i.e. within several cm). The wave coupling is the process by which the power emanating from the radiating structure in the form of a vacuum electromagnetic wave is transferred to the plasma species. This electromagnetic wave can excite plasma waves of various types: (1) Electromagnetic waves are waves for which the propagation does not rely on the plasma species. (2) Electrostatic waves are characterized by an oscillating electric field in the direction of propagation. This electric field induces an oscillating plasma current and associated space charge, which itself is responsible for a response electric field further away in the plasma. (3) Magnetohydrodynamic (MHD) waves are characterized by an oscillating magnetic field which induces a plasma current, itself inducing a magnetic field further away in the plasma. It should be emphasized that such a separation is an idealized view: actual plasma waves generally involve several of these processes at the same time (Stix, 1992). As a result, the separation between the reactive part of the wave power, reversibly exchanged between the electromagnetic field and the plasma species and therefore linked to wave propagation, and the resistive part of the wave power, irreversibly transferred to the plasma species and therefore responsible for plasma heating, is in practice a delicate task (Swanson, 2003).

Wave propagation

There exist several methods to solve the wave equation, Eq. (3). When the wavelength λ remains much smaller than the typical space scales characterizing the plasma equilibrium quantities, L_B , the *WKB approximation* is applicable, allowing Eq. (3) to be solved by ray-tracing or beam-tracing (quasi-optical methods). On the other hand, regimes in which λ becomes comparable to, or larger than,

L_B , or in which the wave undergoes reflection or resonance phenomena during its propagation make it necessary to solve Eq. (3) directly, by resorting to a full-wave approach. Although more intensive numerically, modern computers allow this type of calculation to be performed in a routine fashion, including for higher frequency waves.

However, in all cases, considerable insight can be gained by analyzing the dispersion relation corresponding to the wave equation. This relation is obtained by assuming that the plasma is stationary and homogeneous. Whereas the former assumption is relatively safe in the context of plasma heating by RF waves, the homogeneity hypothesis is often questionable. Despite this limitation, the dispersion relation is always very useful to analyze wave propagation in plasmas. Writing the local electric field as a monochromatic plane wave characterized by wavevector, $\mathbf{k}$, i.e. $\mathbf{E}(\mathbf{r}, t) \propto \exp(i(\mathbf{k} \cdot \mathbf{r} - \omega t))$, the dispersion relation takes the generic form, $D(\omega, \mathbf{k}) = 0$, and therefore expresses an implicit relation between the wave frequency, ω , and wavevector, $\mathbf{k}$, or equivalently the refractive index, $N \equiv kc/\omega$. Usually, multiple solutions to $D(\omega, N) = 0$ at a given point in the medium are possible, indicating the potential presence of several modes, each one characterized by a different dependence of N on the plasma parameters (density, magnetic field ...). Once a given solution (or mode) is chosen, the dispersion relation can be used in the wave equation to deduce the wave polarization, i.e. the ratio between the various components of the wave electromagnetic field. Among these components, the parallel, $E_{\parallel}$, left-handed, E_+ , and right-handed, E_- , turn out to be of particular importance because they physically correspond to a wavefield oscillating in a direction parallel to the magnetic field ($E_{\parallel}$), and rotating in the same direction as ions (E_+) or electrons (E_-).

In magnetically confined plasmas, the projection of N along the magnetic field, $N_{\parallel}$, is essentially determined by the antenna geometry, and usually does not vary much as the wave propagates. The perpendicular component, $N_{\perp}$, on the other hand, largely depends on the plasma parameters. It is instructive to investigate wave propagation in terms of $N_{\perp}$ in the context of the cold plasma theory, in which all species are assumed to have zero temperature. In such plasmas, the dispersion relation can be written as $D(\omega, N_{\perp}) = A(x)N_{\perp}^4 + B(x)N_{\perp}^2 + C(x)$, where the coefficients A , B and C are function of the local plasma parameters (Stix, 1992), parametrized here by the variable x . The consequence is that only two modes can exist at a given point, x , in a cold plasma. Furthermore, there may exist points verifying $N_{\perp}^2(x) = 0$, called cut-offs. In this situation, the wave can only propagate up to the cut-off where it is reflected. Points such that $N_{\perp}^2(x) \rightarrow \infty$ are called resonances.

The inclusion of finite temperature effects in the model regularizes the singular behavior observed at cold resonances. Wave absorption, a phenomenon absent in the cold plasma theory, takes place and results in an irreversible power transfer through the resonance mechanism involving the wave field and the particle motion. Retaining thermal effects also has the consequence of allowing more than two modes to propagate in the plasma. In particular, it is possible to encounter situations for which two modes characterized by $N_{\perp 1}$ and $N_{\perp 2}$ propagating independently reach a point such as $N_{\perp 1} = N_{\perp 2}$. In this case, part of the wave power in a given mode can be partially transferred to another mode, in a process called mode-conversion.

In magnetic fusion plasmas, these three processes (i) wave cut-off, (ii) resonant wave absorption and (iii) mode conversion, are quite prevalent and therefore need to be included in any description of wave propagation and absorption (Stix, 1992).

Wave absorption

As discussed previously (see the “Quasilinear description of RF heating” section), wave-particle resonance occurs when parameters characterizing a wave (ω , $k_{\parallel}$) and parameters characterizing a given plasma species are such that a resonance condition is fulfilled. $k_{\perp}$, on the other hand, is determined by the dispersion relation. Typically, such a resonance occurs when the wave frequency matches the local gyration motion of electrons or ions, $\omega = \Omega_{cs} + k_{\parallel}v_{\parallel}$ (cyclotron resonance), one of its harmonics, $\omega = p\Omega_{cs} + k_{\parallel}v_{\parallel}$ (harmonic cyclotron resonance, with $p > 1$) or the parallel particle motion, $\omega = k_{\parallel}v_{\parallel}$ (Cerenkov resonance). A synchronization process takes place between the wave-field and the particle motion. However, this process is reversible by nature. The transformation of reactive power to resistive power through the wave-particle resonance requires one or several mechanisms responsible for decorrelating the field oscillation from the plasma particle response. These processes are often referred to under the generic term of phase-mixing mechanisms. One such decorrelation process is the Coulomb collisions themselves. By their stochastic nature, collisions are clearly able to destroy any wave/particle correlations. However, experimental evidence pointed to the possibility of wave damping even in collisionless plasmas, triggering an intense effort to interpret these results and identify non-collisional damping mechanisms.

Landau damping

Non-collisional damping has been the center of vigorous debates. Several mathematical derivations have been put forward to describe this phenomenon. However, L. Landau is to be credited for the unambiguous explanation of this effect in 1946 (Landau, 1946; Ryutov, 1999). The mathematical demonstration is rather subtle and involves causality as a key element. The underlying physics idea can be understood by considering a particle with initial parallel velocity $v_{\parallel 0}$ in the presence of an electromagnetic field characterized by phase velocity, $v_{\phi} = \omega/k_{\parallel}$. A resonance occurs when the Cerenkov resonance condition, $\omega = k_{\parallel}v_{\parallel 0}$, is fulfilled. More precisely, during the process, particles with velocities near the wave phase velocity feel the wave effect, and see their motion modified in the synchronization process with the field. It can then be shown that in this case, the particle is either accelerated or decelerated with equal probability. As such, no net acceleration is imparted by the wave power. However, when considering an assembly of particles, the slower particles, i.e. those with $v_{\parallel 0} < \omega/k_{\parallel}$, which are accelerated, tend to feel the wave resonance with more intensity. On the other hand, those decelerated tend to resonate even less with the wave. Statistically, therefore, wave power will be employed to accelerate slower particles. The symmetrical situation involves faster particles, i.e. those with $v_{\parallel}$

$0 > \omega/k_{\parallel}$. In contrast with the previous case, the decelerated particles will become more resonant than the accelerated ones. As a result, kinetic energy from the particles will tend to amplify the wave. However, fusion plasmas are typically characterized by Maxwellian distributions, which have a decreasing dependence with parallel velocity, $v_{\parallel}$. The consequence is that slower particles are more numerous than faster particles, so that the net result of the two processes described previously is an absorption of the wave by the particles. This explains that γ , the wave damping rate, which characterizes the field attenuation with time, i.e. $E \propto \exp(-\gamma t)$, depends linearly on the slope of the distribution function considered at the wave-particle resonance, i.e. $\gamma \propto df_s/dv|_{v_{\parallel}=\omega/k_{\parallel}}$. The result of this interaction on the distribution function of the interacting species is described by Eq. (4), and takes the form of a local flattening in velocity space around the resonance.

Cyclotron damping

Cyclotron damping is related to the process of Landau damping. The resonance condition, however, involves the particle gyromotion, and can be written as $\omega = p\Omega_{cs} + k_{\parallel}v_{\parallel}$, with p a non-zero integer. The cyclotron resonance occurs when the wave frequency matches the cyclotron frequency Ω_{cs} ($p = 1$), i.e. the frequency characterizing the particle gyro-motion or one of its harmonics ($p > 1$). The last term, $k_{\parallel}v_{\parallel}$, is the Doppler shift correction caused by the parallel motion of the particles along the field lines. Although it bears some similarities with Landau damping, the dependence of the cyclotron frequency with the confinement magnetic field magnitude, B_0 , induces essential differences in the resonance phenomenon. By construction, B_0 has a spatial dependence, proportional to $1/R$ (the distance to the torus revolution axis) in tokamaks—but more complex in stellarators. The result is that the resonance only occurs in a spatially localized region. The particles having periodical motion, the resonance occurs at multiple times as the particle travels through the plasma, which introduces another possible decorrelation mechanism in the system. The other fundamental difference is that the cyclotron motion is, by nature, perpendicular to the magnetic field. The resulting velocity-space diffusion occurs mainly in the perpendicular direction, which tends to increase the perpendicular particle velocities. The heated distribution functions in velocity space can therefore exhibit pronounced anisotropies, with a perpendicular energy content often significantly exceeding the parallel energy content.

Wave-induced current drive

The process of RF-induced current drive (CD) is inherently linked to electron Landau damping. A wave characterized by angular frequency, ω , and parallel wavevector, $k_{\parallel}$, can resonate with electrons having a parallel velocity fulfilling the Cerenkov resonance condition, $v_{\parallel} = \omega/k_{\parallel}$. The consequent absorption of an energy quantum, $\Delta E = \hbar\omega$, by an electron results in an increase of its parallel momentum, $\Delta p_{\parallel} = \hbar k_{\parallel} = k_{\parallel}\Delta E/\omega$. Therefore, an injected wave characterized by an asymmetric spectrum in terms of $k_{\parallel}$ will impart momentum to the electrons, thereby inducing a net parallel current.

As illustrative as this physics picture may be, it must be stressed that the mechanism of momentum transfer from the wave to the plasma described previously is not the dominant one in RF current drive applications. Indeed, it turns out that even waves imparting only perpendicular momentum to the electrons can drive current in a relatively efficient fashion. This results from the fact that wave-induced current drive relies for the most part on the variation of the plasma collisionality with the energy of resonant particles. Therefore, creating a population of electrons characterized by an excess of perpendicular energy can be exploited for current drive purpose, as long as the distribution function is asymmetric for the parallel velocity. This process is known as the Fisch-Boozer mechanism (Fisch, 1987).

A figure of merit of any current drive method is the amount of current driven, Δj , for a given amount of power expended, p . If we consider an electron receiving parallel momentum, $\Delta p_{\parallel}$, from the wave, the corresponding current increase is $\Delta j = -e\Delta p_{\parallel}/m_e$, with e the absolute value of the electron charge and m_e the electron mass. Collisions, on the other hand, tend to oppose this momentum increase, a process which can be characterized by the counteracting force, $F = -v_e\Delta p_{\parallel}$, with v_e an effective collision frequency. By identifying the wave power spent to the work variation required to maintain the current drive process, we obtain the elemental current drive efficiency:

$$\Delta j/p = e/m_e v_e v_{\parallel}. \quad (7)$$

In order to maximize the efficiency, it would therefore seem natural to target thermal electrons, characterized by relatively low values of $v_{\parallel}$. Early current drive schemes, using *Alfvén waves*, were based on this idea. However, a large fraction of thermal electrons is trapped in the magnetic mirrors constitutive of the magnetic confinement structure, and therefore do not complete full revolutions in the toroidal direction. Consequently, they are unable to carry any parallel current and the resulting efficiency is too low to be of any interest. By contrast, in the range of velocities characterizing superthermal (or energetic) electrons, the effective collision frequency, v_e , varies as $(1/v_{\parallel})^3$, so that by virtue of Eq. (7), the efficiency increases with $v_{\parallel}^2$. Finally, superthermal electrons also suffer less from trapping effects than thermal electrons. As a result, modern RF-based current drive schemes, i.e. those exploiting lower hybrid and electron cyclotron waves, are based on energetic electrons.

Finally, it should be noted that whereas Eq. (7) is interesting from a physics standpoint, it is hardly adequate to characterize the global efficiency of a given CD system, i.e. to obtain an estimate of the level of driven current corresponding to the power available on a given fusion device. For this purpose, it is worthwhile realizing that the absorbed power (in W) scales as $P_{abs} \sim 2\pi R \pi a_0^2 p_{abs}$, whereas the total current (in A) scales as $I_{CD} \sim \pi a_0^2 j$, with R the major radius, a_0 the minor radius, p_{abs} the power density (in

W m^{-3}) and j the current density (in A m^{-2}). Accordingly, a useful quantity is the normalized current drive efficiency, a global figure of merit valid for any CD scheme and defined as $\eta_{\text{CD}} \equiv n_e R I_{\text{CD}} / P_{\text{abs}}$, with n_e the appropriately averaged electron density.

Plasma heating and current drive by energetic ions

Regardless of the heating method employed, collisions often play an essential role since they are responsible for the transfer of power between the energetic particles and the thermal plasma species. Indeed, one of the most prevalent processes in modern heating and current drive applications involves the collisional relaxation of energetic ions, injected by the NBI system, born from fusion reactions or generated by RF acceleration of initially thermal species. The transfer of energy occurring between these energetic ions and the background plasma results from the various collisional processes at play. Their respective influence depends on the initial energies of the injected particles, E_f , on the Spitzer slowing-down time, τ_{se} , and on the critical velocity, E_c . It must be pointed out that energetic ions (NBI-driven, RF-driven or fusion products) can trigger instabilities, potentially inducing a radial redistribution of these ions. The impact of these processes on heating, current drive efficiency and fusion performance, as well as control schemes aimed at minimizing them (including using RF waves), is currently an active topic of experimental and numerical studies to prepare for the operation of next-step devices (Gorelenkov and Sharapov, 2021).

Neutral beam heating and current drive

Neutral beam injection is an auxiliary heating method which involves the production of high-energy ions in an accelerator, and their neutralization as they are ejected towards the confined plasma. These neutral particles are immune to the effects of the magnetic field in which the plasma is confined, and can thus penetrate to the plasma core. They are progressively re-ionized as they travel through the hot plasma. Since they are injected at an energy much larger (typically in the range 50–150 keV in ongoing devices, and 1 MeV in ITER) than the typical confined plasma particle energies, they slow down through collisions with these particles. Adapted numerical codes (Schneider et al., 2011) taking into account the beam and plasma parameters are required to compute the neutral beam and corresponding power deposition. The NBI system installed in JET, as well as an illustration of a typical power deposition profile in the plasma is shown in Fig. 2.

Consistently with the collisional relaxation process discussed in the “Kinetic theory elements” section, the result of plasma heating by NBI ions depends on the background plasma and injected ion parameters. As an illustration, NBI ions with typical injection energies of $E_f \sim 100$ keV are used in JET and result in dominant thermal ion heating (see Table 1). In ITER, on the other hand, the plasma size and density make it necessary to resort to much higher beam energies to deposit the beam power in the plasma core. Negative NBI ions with $E_f \sim 1$ MeV have been adopted to fulfill this requirement, and tend to create a balanced heating on thermal electrons and ions, with little dependence on whether the background plasma consists of D ions only, or of mixed D-T fuel.

Depending on the NBI system geometry, in some situations, it is possible to inject energetic ions with a significant component of the velocity direction parallel to the confinement magnetic field, i.e. able to impart a significant amount of parallel momentum to the plasma. As a result, a finite level of toroidal current is driven, a scheme referred to as Neutral Beam Current Drive (NBCD). Assuming beam ions with mass, m_f , and density, n_f , the parallel momentum injected in the system is $m_f n_f \langle v_{\parallel} \rangle$, the average being performed on the (injected) energetic NBI ion distribution. Because of collisional relaxation, the beam ions will transfer this momentum to the background species through friction. Assuming, for simplicity a situation where $E_f \gg E_c$, this relaxation essentially takes place on electrons. The subsequent force on electrons in the parallel direction tends to increase their parallel momentum. In a stationary regime, the friction with thermal ions compensates this variation of parallel electron momentum. Taking into

Fig. 2 NBI heating in the JET tokamak. This device is equipped with two separate NBI injectors located in octants 4 and 8, each consisting of eight beams arranged in a tangential bank and a normal bank (Source: EUROfusion). In the inset is shown an illustration of the power deposition profile in the plasma corresponding to the tangential bank of the injector located in octant 8.

account the respective relaxation times of these processes and plasma quasi-neutrality, it can be shown that the resulting driven current takes the form $J_{\text{NBCD}} = J_f(1 - Z_f/Z_i)$, with $J_f = Z_f n_f e \langle v_{\parallel f} \rangle$ the current carried by the beam ions, and Z_f (resp. Z_i) the charge number of beam (resp. thermal) ions. In many situations, Z_f and Z_i are comparable, which induces a large reduction in the NBI driven current because of the friction exerted by the background species on the energetic ions. A more accurate description of the process shows that the current drive efficiency predicted is generally larger than this analytical estimate. A first correction consists of taking into account trapped electron effects, which, in the case of NBCD, reduce the amount of electron current resulting from the cancellation of the beam current, and therefore entail an increase of the net efficiency (Fisch, 1987). The largest efficiency obtained to date is $\eta_{\text{CD}} = 0.155 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$ using 360 keV negative ion NBI in the JT-60U tokamak (Inoue et al., 2021). Predictions indicate that efficiencies of the order $\eta_{\text{CD}} \sim 0.2 - 0.4 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$ should be achievable in ITER (Gormezano et al., 2007).

Finally, it must be pointed out that NBI also plays an essential role in driving toroidal rotation of the plasma, which is known to have a favorable effect on confinement (Jenko, 2021) and MHD stability (Lao et al., 2021) in ongoing devices. Predictions indicate that this effect will be less significant in reactor-scale devices, however. A larger plasma volume and density translates into a larger moment of inertia, whereas the higher beam ion energy results in a reduction of the injected torque.

Burning plasmas

Burning plasmas consist of a mix of D-T fuel, which produces alphas born at 3.5 MeV able to heat the background species in a self-sufficient fashion (or nearly so). So far, only the tokamaks TFTR (USA) and JET (European Union) have operated with mixed D-T fuels. In these devices, the alpha power production remained small compared to auxiliary heating, making the effect of self-heating by alphas difficult to isolate. ITER is the first magnetic fusion device expected to contain a genuine burning plasma. In Table 2 are compared the situations in JET and in ITER with respect to plasma heating by the alphas. In the two cases, alphas predominantly heat the background electrons. However, the larger density (and thus collisionality) in ITER high-performance scenarios results in a more balanced heating partition between the electrons and the fuel ions, which is favorable for plasma fusion performance.

Plasma heating and current drive by radiofrequency waves

Ion cyclotron (IC) range of frequency

In the ion cyclotron range of frequencies (ICRF, 20–80 MHz), the antenna consists of a set of metallic straps enclosed in a box located at the edge of the magnetized medium and is capable of exciting a wave propagating in the plasma. In this frequency range, the system plasma-antenna must be considered as a global electrical circuit. This has the practical consequence that the antenna needs to be adapted to the plasma, by ensuring that their respective impedances match. In general, coupling ICRF power to the plasma is a delicate problem and a considerable effort is being devoted to this topic.

Examination of the dispersion relation in this range of frequencies reveals the existence of two waves, the so-called slow wave and fast magnetosonic wave. The slow wave, characterized by $N_{\perp}^2 \sim -\omega_{pe}^2/\omega_{ci}^2$ is evanescent with a small wavelength ($\lambda < 1 \text{ mm}$), which means that it is useless for plasma heating since it cannot propagate away from the antenna vicinity. Here, $\omega_{ps}^2 = n_s q_s^2/m_s \epsilon_0$ is the squared plasma frequency and $\omega_{ci} = Z_i e B_0/m_i$ is the cyclotron frequency of the main ions. It should be noted that the slow wave plays an important role in the problem of wave coupling, and in the development of performance limiting electrical sheaths, which can occur in some situations. The fast wave dispersion relation for a cold plasma is given by $N_{\perp}^2 \sim (N_{\parallel}^2 - R)(N_{\parallel}^2 - L)/(S - N_{\parallel}^2)$ with $R \sim -(c/v_a)^2 \omega_{ci}/(\omega - \omega_{ci})$, $L \sim (c/v_a)^2 \omega_{ci}/(\omega + \omega_{ci})$ and $S \sim -\omega_{pi}^2/(\omega^2 - \omega_{ci}^2)$, v_a being the Alfvén velocity. It is clear from these expressions that the fast wave exhibits two cut-offs: the right cut-off, $N_{\parallel}^2 = R$, the left cut-off, $N_{\parallel}^2 = L$; and a resonance called the Alfvén (or hybrid) resonance, $N_{\parallel}^2 = S$. The presence of the right cut-off implies that the fast wave does not propagate below a finite density, $n_e \sim 1 \times 10^{18} \text{ m}^{-3}$, which corresponds to a location significantly inside the plasma scrape-off layer. In other words, like the slow wave, the fast wave is evanescent near the plasma edge. However, with a space decay typically of the order of 10 cm, a significant fraction of the power can tunnel through the evanescence layer to reach the right cut-off, and propagate onward to the plasma core. The left cut-off, on the other hand, is located well inside the plasma core. Once coupled to the plasma, the fast wave is able to propagate between these two cut-offs, where it remains trapped until dissipation mechanisms damp the power.

The dominant damping mechanism of the fast magnetosonic wave is cyclotron damping by ions fulfilling the resonance condition, $\omega = p\omega_{ci} + k_{\parallel}v_{\parallel f}$. The corresponding generic form of the quasilinear diffusion coefficient (see Eq. 6) is

Table 2 Collisional plasma heating resulting from D-T alphas in JET and in ITER.

Background plasma/test particle	Initial energy (keV)	Critical energy (keV)	Spitzer time (s)	Thermalization time (s)	Fraction of power to ions/to electrons
JET DT/alpha	3500	330	0.73	0.86	0.17/0.83
ITER DT/alpha	3500	826	1.32	1.00	0.35/0.65

$$D_{ql} = A \sum_p |E_+ J_{p-1}(k_\perp \rho_i) + E_- J_{p+1}(k_\perp \rho_i)|^2 \delta(\omega - p\omega_{ci} - k_\parallel v_{\parallel i}), \quad (8)$$

with E_+ (resp. E_-) the left-handed (resp. right-handed) component of the electric field. J_p is the Bessel function of order p and $\rho_i = v_\perp / \omega_{ci}$ the (heated) ion Larmor radius. This expression shows that to lowest order, damping is determined by the left-handed component of the electric field, rotating in the ion direction. Furthermore, for small arguments, $J_p(x) \sim x^p$. In other words, fundamental heating ($p = 1$) is in principle very efficient since D_{ql} is at lowest order independent of $k_\perp \rho_i$. From a wave propagation standpoint, the situation described previously would seem to be ideal, since the cyclotron layer $\omega = \omega_{ci}$, around which the fundamental damping occurs, is always located between the two cut-offs. However, it turns out that the dispersion relation also dictates that the ratio of the left to right polarized components of the wave field be such as $E_+/E_- = (N_{\parallel i}^2 - R)/(N_{\parallel i}^2 - L)$, which goes to zero as $\omega \rightarrow \omega_{ci}$. The result is that fundamental damping of the fast wave is a weak phenomenon, forbidding its applicability in a “pure” plasma, i.e. a plasma including a single ion species.

This problem can be overcome by using a harmonic of the cyclotron resonance, i.e. $p = 2$ or more. This scheme, named harmonic heating, does not suffer from the same limitation as fundamental damping and can be used even in pure plasmas. However, Eq. (8) shows that the corresponding term is now proportional to $k_\perp \rho_i$, which depends itself on the pressure of the heated ion. To be efficient, second harmonic heating thus requires an already significant temperature of the heated ions. Nevertheless, second harmonic IC resonance heating (ICRH) has been successfully employed in various tokamaks as a heating method, and second harmonic tritium heating is a scenario which is planned to be used in ITER (Gormezano et al., 2007).

A possibility to exploit fundamental heating despite the limitation exposed previously is to introduce a small fraction (typically 2–8%) of a different ion in the plasma in addition to the majority ion and to perform fundamental cyclotron heating of this minority ion, hence the denomination: minority heating regime. In this case, it is possible to show that the left cut-off, $N_{\parallel i}^2 = L$, and the hybrid resonance, $N_{\parallel i}^2 = S$, are located very close to each other. The advantage is that the field polarization is now mainly imposed by the majority ion, and therefore E_+ does not cancel at the fundamental minority resonance. The second advantage is that the fundamental cyclotron layer, $\omega = \omega_{ci}$, is very close to the cut-off/hybrid resonance couple. This results in a locally large electric field magnitude and associated stored reactive power. The outcome is efficient heating of the minority species, and this scheme has been routinely used in magnetic fusion devices for decades. The most widespread scenario is hydrogen heating in deuterium plasmas, with a typical hydrogen concentration of 3–5%. Since the power per absorbing ion is quite large, minority heating schemes tend to create very energetic ion populations and one relies on collisional relaxation on thermal electrons and/or ions for plasma heating. In ITER, fundamental heating of helium-3 (^3He) ions is currently one of the envisaged schemes to heat DT plasmas with ICRF waves. It is even envisaged to initiate the heating phase by injecting a small quantity of ^3He ions in the plasma. Minority damping, which is to lowest order independent of the heated ion temperature, will dominate and increase the ion temperature. Once the tritium temperature is sufficient and as the ^3He concentration naturally decreases, second harmonic tritium damping (located at the same position, since $\omega = \omega_{c3\text{He}} = 2\omega_{cT}$) is expected to take over, thus allowing smaller quantities of the expensive ^3He gas to be used. Fig. 3 illustrates the principle of ICRF heating in a tokamak such as JET, as well as an actual calculation of the left-handed

Fig. 3 Depiction of IC wave heating in a tokamak plasma consisting of 95% deuterium + 5% hydrogen. (a) General principle illustrated via a schematic wave propagating from the antenna across the plasma magnetic field surfaces (gray lines). The red color corresponds to locations where significant wave damping occurs; (b) Full-wave calculation of the left-handed electric field (shown in color contours). The vertical dashed lines show the approximate location of the fundamental ion cyclotron resonance layer. Efficient wave absorption by the minority ions results in a low amplitude residual electric on the left of the resonance.

electric field in a typical hydrogen minority heating scenario performed with a full wave code adapted to the description of waves in the Alfvén and IC range of frequencies (Dumont, 2009).

More recently, the so-called 3-ion scheme has been proposed and tested in several tokamaks (Kazakov et al., 2017). This involves the targeted heating of a third ion species characterized by charge number, Z , and mass number, A , in a plasma with two ion species (Z_1, A_1, Z_2, A_2). It can be shown that when the condition $Z_1/A_1 < Z/A < Z_2/A_2$ is satisfied, very efficient damping by the third species can be obtained, as long as it is present in very small concentrations (typically 0.1–1%). This scheme has been proposed to generate energetic ions in stellarators in order to experimentally document their confinement, and to provide efficient ICRF heating during phases of ITER operation at reduced magnetic field. It is also envisaged to use this scheme for ITER D-T plasmas, exploiting the natural presence of the beryllium (Be) impurity in the plasma. In a D-T mixture, Be satisfies $Z_T/A_T = 1/3 < Z_{Be}/A_{Be} = 4/9 < Z_D/A_D = 1/2$. The advantage is that the heavy Be ions tend to heat the fuel ions by collisions, rather than the electrons, which is beneficial in terms of fusion power production. It must be pointed out that, owing to its relatively novel character, this scheme is not as well established as the more traditional minority or harmonic heating schemes. Nevertheless, its flexibility and the fact that it proposes to exploit impurities naturally present in the plasma make it an appealing tool for future magnetic fusion devices.

A comparison of thermal plasma heating by typical RF-accelerated ions is shown in Table 3.

By increasing the minority concentration to ~10–15%, the fundamental cyclotron layer, $\omega = \omega_{ci}$, on the one hand and the cut-off/resonance structure on the other hand move further apart. In this case, it is possible to have a substantial part of the fast wave power tunnel through the evanescence layer and undergo a mode conversion towards the pressure driven Ion Bernstein Wave (IBW). In this mode conversion regime, one relies on the damping of the small wavelength IBW by the thermal electrons to obtain a localized electron heating source. It should be pointed out that despite good results obtained in several tokamaks, this scheme remains difficult to implement in practice, and requires delicate tuning of the magnetic field, minority concentration and antenna toroidal phase spectrum.

The reader should be aware that the physics of IC waves is very rich and many topics related to their use in fusion plasmas have been omitted. Among these, Fast Wave Electron Heating (FWEH), which has been successful in some past experiments, relies on the damping of the fast wave by the thermal electrons. FWEH is achieved by excluding all relevant cyclotron resonance layers by a careful choice of frequency/magnetic field combination. Using an asymmetric toroidal phase spectrum, furthermore, allows Fast Wave Current Drive (FWCD) to be achieved. FWEH is not envisaged in ITER, because the exclusion of all relevant cyclotron layers does not appear to be achievable in such a large device. FWCD, on the other hand, can be interesting since a moderate level of central non-inductive current can be obtained as a by-product of the IC heating wave damping on the electrons, simply by modifying the antenna current distribution and thus the toroidal phase spectrum. Other possibilities include MHCD (Minority Heating Current Drive), which relies on finite orbit width effects to drive a current related to the energetic ions; MCCD (Mode Conversion Current Drive) obtained by exciting a mode-converted wave with an asymmetric spectrum; HHFW (High Harmonic Fast Wave heating) relying on high frequency fast waves for localized electron heating/current drive, using traveling wave antennas to optimize wave coupling and toroidal directivity. To this day, these schemes are not considered as workhorse ICRH scenarios for ITER.

Lower hybrid (LH) range of frequency

Between 1 and 10 GHz, lower hybrid (LH) waves can be used for non-inductive current drive in tokamaks. In this frequency range, $\omega_{ci} \ll \omega \sim \omega_{LH} < \omega_{ce}$, with ω_{LH} the LH resonance frequency $\omega_{LH} \sim \omega_{pi}/(1 + \omega_{pe}^2/\omega_{ce}^2)^{1/2}$. The cold dispersion relation reveals two waves: the fast wave already discussed for IC waves, is useless for plasma heating because the evanescence region between the antenna and the R-cutoff is too wide compared to the wavelength in this range of frequencies; the slow wave, on the other hand, is characterized by the approximate dispersion relation $N_{\perp}^2 \sim N_{\perp}^2(m_p/m_e)\omega_{LH}^2/(\omega - \omega_{LH}^2)$. This expression shows that for given a magnetic field and density, the LH wave propagates at a finite angle, $\theta = \theta(\omega)$, with respect to the magnetic field direction. This kind of configuration is known as a resonance cone wave (Swanson, 2003). A further examination of the dispersion relation shows that the electric field polarization is essentially along the wave vector. The LH wave is therefore an electrostatic wave and does not have any magnetic field component associated to it.

Originally, the idea was to target ion heating by damping of the wave near the LH resonance, hence the name of this scheme. Indeed, as discussed in the “Wave propagation” section, this cold resonance is characterized by $k_{\perp} \rightarrow \infty$, so that efficient heating of ions at relatively low velocities, $v_{\perp} \sim \omega/k_{\perp}$ (i.e. thermal) by perpendicular Landau damping was anticipated. However, experimental evidence pointed to several phenomena preventing this damping mechanism from taking place. For instance, the large values of $N_{\perp}$ attained when approaching this resonance result in the parametric decay of the wave, a non-linear effect responsible

Table 3 Collisional plasma heating resulting from RF-accelerated ions in JET and in ITER.

Background plasma/test particle	Initial energy (keV)	Critical energy (keV)	Spitzer time (s)	Thermalization time (s)	Fraction of power to ions/to electrons
JET D/H	2000	93	0.73	1.11	0.09/0.91
JET D/He3	700	280	0.54	0.29	0.49/0.51
ITER DT/He3	700	619	0.99	0.26	0.72/0.28
ITER DT/Be	700	1858	0.74	0.05	0.92/0.08

for a degraded wave penetration in the plasma. Fortunately, it turns out that efficient wave damping by electrons satisfying the Cerenkov resonance, $v_{\parallel} \sim \omega/k_{\parallel}$, is also achievable in this range of frequencies, provided a slow wave with $N_{\parallel}^2 > 1$ can be excited from an external antenna. Like the fast wave, the slow wave is subject to a low-density cut-off at $\omega \sim \omega_{pe}$, but the corresponding value is of the order 10^{17} m^{-3} in typical conditions. As a result, the evanescence region is quite thin compared to the wavelength in vacuum, and it is possible to design efficient slow wave antennas with the required toroidal periodicity.

Once the slow wave has entered the plasma, it propagates towards the plasma center, with a corresponding increase of $N_{\perp}$. In this range of frequencies, however, if $N_{\parallel}$ is smaller than a given $N_{\parallel}^*$ which depends on density and magnetic field, a confluence between the fast and slow waves takes place in the plasma. Unless damping takes place before the slow wave reaches this confluence point, the converted fast wave propagates back towards the antenna. For all practical purposes, therefore, $N_{\parallel} > N_{\parallel}^*$ places a restriction on useful parallel refractive indices, densities and magnetic fields required for the slow wave to reach the plasma core (Brambilla, 1998), and is known as the Stix-Golant accessibility condition.

Typical values of the parallel refractive indices achieved with standard LH antennas are $N_{\parallel, \text{ant}} \sim 2$. For a plasma characterized by a core electron temperature, $T_e = 10 \text{ keV}$, the range of velocities of the resonant electrons is therefore found to be $v_{\parallel}/v_{th,e} = c/(N_{\parallel}v_{th,e}) \sim 2.5$. For a Maxwellian distribution function, the corresponding number of electrons is very small. LH wave damping therefore relies on the changes of $N_{\parallel}$ as it propagates. Indeed, it can be shown that various effects, among which are toroidicity and spectral broadening by density fluctuations, cause $N_{\parallel}$ to vary during the propagation (Peysson et al., 2017). At some point, $N_{\parallel}$ becomes sufficiently large for Landau damping by electrons with parallel velocities, $v_{\parallel} \sim v_{th,e}$, to take place. The regime in which the rays representative of the LH wave have to travel a long distance around the torus before damping is known as the multi-pass regime, and characterizes most past and current experiments using LH waves. If, on the other hand, T_e and/or $N_{\parallel}$ are sufficiently large from the onset, the wave can be absorbed on its first pass towards the plasma core, a situation referred to as the single-pass regime, which is what would happen in a next-step tokamak containing a very hot plasma. Fig. 4 illustrates the difference between these regimes in two discharges conducted in the Tore Supra tokamak, as computed with a Fokker-Planck code associated to a ray-tracing code (Decker et al., 2014).

In all cases, absorption initially occurs at large values of $N_{\parallel}$, and involves electrons close to the thermal velocity. An energetic electron tail is progressively created starting from these thermal electrons, eventually extending up to superthermal electrons at energies up to a few hundred keV. The quasilinear diffusion induced by the wave is in the parallel velocity direction. As a result, the electron distribution function features a flat region in terms of $v_{\parallel}$, known as the quasilinear plateau. Using an asymmetric $N_{\parallel}$ spectrum therefore results in an asymmetric electron distribution function with respect to $v_{\parallel}$, with a substantial superthermal population. Electrons diffusing in the parallel direction do not experience trapping effects as much as electrons diffusing in the perpendicular direction. Furthermore, in addition to creating an asymmetric resistivity, the LH directly transfers parallel momentum to the electrons. These advantages explain the large LH current drive (LHCD) efficiency achieved in several devices, up to $\eta_{\text{LHCD}} = 0.34 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$ in the large tokamaks JET and JT-60U. Projections for ITER predict that $\eta_{\text{LHCD}} \sim 0.24 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$ could be achieved, with a deposition profile peaked significantly off-axis (normalized radius ~ 0.7) because of the high density and temperature (Gomezano et al., 2007). Despite these results, at this point, uncertainties related to the LH wave penetration and current drive efficiency in dense plasmas, as well as parasitic wave damping by the fusion alphas in a D-T plasma, make their future applicability in reactors uncertain.

Electron cyclotron (EC) range of frequency

Electron cyclotron (EC) waves are typically injected in the frequency range 50–200 GHz, which coincides with the fundamental cyclotron resonance of electrons in most modern magnetic fusion devices. Lower field operation opens the possibility to use

Fig. 4 LH wave current drive in the Tore Supra tokamak. Ray trajectories are shown projected in the poloidal cross-section of the tokamak, but also propagate toroidally around the plasma. (a) In a relatively dense and cold plasma (volume averaged density $\langle n_e \rangle \sim 3.8 \times 10^{19} \text{ m}^{-3}$, central temperature $T_{e0} \sim 2.4 \text{ keV}$), the LH wave is in the multi-pass regime and the rays propagate on large distances before damping takes place. (b) In a less dense and hotter plasma, on the other hand ($\langle n_e \rangle \sim 1.3 \times 10^{19} \text{ m}^{-3}$, $T_{e0} \sim 5.7 \text{ keV}$), damping occurs relatively early during the propagation and the single-pass regime is approached.

harmonic schemes. In this frequency range, $\omega_{ci} \ll \omega \sim \omega_{ce} \sim \omega_{pe}$. The wave is exclusively damped by resonant electrons. For these frequencies/wavelengths, the propagation is quasi-optical and is quite adequately described by ray-tracing or beam-tracing codes. This has the considerable practical advantage of allowing a coupling of the wave to the plasma using an antenna located at some distance, generally consisting of a set of steerable mirrors to vary the deposition location, and possibly to use these waves for current drive by injecting them obliquely with respect to the magnetic field.

The dispersion relation reveals two distinct waves, called the ordinary and extraordinary modes. The ordinary (O) mode has the simple dispersion relation, $N_{\perp}^2 = 1 - \omega_{pe}^2/\omega^2$, showing that it can propagate to the plasma core, at least up to the plasma cut-off, $\omega = \omega_{pe}$, which corresponds in practice to central densities larger than 10^{20} m^{-3} . Fundamental absorption of the ordinary mode is therefore a viable scheme for most tokamaks, including ITER. The extraordinary (X) mode has the somewhat more complex dispersion relation, $N_{\perp}^2 = (\omega^2 - \omega_R^2)(\omega^2 - \omega_L^2)/(\omega^2(\omega^2 - \omega_{UH}^2))$, with ω_R and ω_L the right and left cut-off frequencies, and ω_{UH} the upper hybrid frequency. The right cut-off prevents the X-mode from reaching the fundamental cyclotron resonance, $\omega = \omega_{ce}$, from the low field side of the plasma. Although conceptually appealing, the solution of installing an antenna on the high field side does not appear to be realistic in the context of a reactor. Alternatively, one can resort to the second harmonic resonance $\omega = 2\omega_{ce}$. The drawback of this method is that the right cut-off, while not preventing the resonance at $\omega = 2\omega_{ce}$ from being reached, imposes a cut-off density which is only 50% of the cut-off density of the O-mode for a given frequency and therefore requires operating a relatively higher frequency. The two schemes envisaged for EC resonance heating (ECRH) and current drive (ECCD) in modern magnetic fusion devices are therefore fundamental ordinary mode heating (O-1) or second harmonic extraordinary mode heating (X-2), and sometimes even third harmonic X-mode heating (X-3).

The fundamental resonance condition for EC waves is given by $\omega = \omega_{ce} + k_{\parallel}v_{\parallel}$, where $\omega_{ce} = eB_0/\gamma m_e$ is the electron cyclotron frequency and γm_e is the electron mass corrected for relativistic effects, which turn out to play a major role in the resonance condition. It can be shown that the resonance curve is an ellipse in velocity or momentum space, $(p_{\perp}, p_{\parallel})$, with $\mathbf{p} = \gamma m_e \mathbf{v}$ the electron momentum. Writing $\omega = \omega_{ce}(R_{\text{res}})$, with R_{res} the resonant position in terms of major radius R , shows that the energy of resonant electrons is given by:

$$E = m_e c^2 \left(R_{\text{res}}/R - 1 + N_{\parallel} p_{\parallel} / m_e c \right) \quad (9)$$

For a given position, R , the resonance parameters ω/ω_{ce} and $N_{\parallel}$ thus locate the interaction in the $(p_{\perp}, p_{\parallel})$ plane, which results in a coupling between the wave damping properties in physical space and the location of distribution function modifications induced by the wave momentum space. The quasilinear diffusion that is induced occurs mainly in the perpendicular direction near the resonance ellipse.

Studying wave damping more carefully requires the calculation of the full hot relativistic dielectric tensor (Brambilla, 1998). Some insight into the damping process can nevertheless be gained by realizing that for EC waves, the electric field-dependent coefficient in the quasilinear diffusion coefficient (Eq. 6) is, to lowest order, proportional to $|d^{(p)}(\mathbf{E})| \sim |v_{\perp} E_{\perp} J_{p-1}(k_{\perp} \rho_e)|^2$, with $E_{\perp}$ the right-handed component of the electric field, J_{p-1} the Bessel function of order $p-1$ and ρ_e the electron Larmor radius. For small arguments, $J_{p-1}(k_{\perp} \rho_e) \sim (k_{\perp} \rho_e)^{p-1}$, showing that fundamental damping does not depend directly on the electron temperature, whereas second harmonic damping is a finite temperature effect. This would seem to indicate that O-1 damping is more efficient than X-2 damping, but, as for IC waves, the electric field polarization near $\omega = \omega_{ce}$ is such that $E_{\perp}$ is relatively small (0 in the cold-plasma approximation), thereby decreasing the absorption strength. This is confirmed by comparing the respective optical depths for the O-1 and X-2 modes, i.e. the ratio between the power crossing the resonance layer and the incident power, which shows that X-2 damping is typically 5–10 times more efficient than O-1 damping. It should be pointed out that despite this difference, this damping is very efficient in both cases, so that the power deposition profiles are essentially always narrow.

Furthermore, as explained previously, EC antennas are composed of steerable mirrors (Farina et al., 2014). As a result, it is straightforward to inject the wave with a certain angle with respect to the magnetic field to (1) locate the damping at a precise position in radius, and (2) drive a finite toroidal current. This is illustrated in Fig. 5. As discussed in the “RF wave propagation and damping” section, even though no parallel momentum is imparted by an EC wave to the plasma since the quasilinear diffusion is in the perpendicular direction, the Fisch-Boozer mechanism still makes EC waves suitable for current drive applications. Successful ECCD in a tokamak requires that the damping take place before the fundamental resonance, so that, by virtue of Eq. (9), it occurs on significantly energetic electrons. In theory, the achievable CD efficiency is only a factor of $3/4$ lower than that attained with LH waves (the difference being due to the absence of any parallel momentum input). However, owing to trapped electron effects and to the relatively modest energies of resonant electrons, ECCD is significantly less efficient than LHCD, except at very high temperatures. The record ECCD efficiency to date, $\eta_{\text{ECCD}} = 0.042 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$, was obtained in JT-60U. In ITER, the EC launcher geometry and plasma parameters should allow $\eta_{\text{ECCD}} \sim 0.2 \times 10^{20} \text{ A W}^{-1} \text{ m}^{-2}$ to be achieved (Gormezano et al., 2007). The good localization of the deposition and the excellent flexibility offered by the injector arguably compensate for this lower global efficiency—the driven current density being locally quite large at a position chosen by an operator or by an automated control system. For this reason, EC waves have a wide range of applications, including current profile control, MHD control, and plasma start-up assist (required for stellarators, useful in large tokamaks to enlarge the domain of parameters for plasma breakdown), and their exploitation should increase further as the technological development of efficient and powerful EC generators advances.

Fig. 5 Schematic of EC wave heating and current drive in a tokamak such as ITER. (a) Poloidal cut; (b) Top view. The beam is shown in blue, with red coloring at locations where significant absorption occurs. The (fictitious) EC steering mirror is shown in magenta, and is used in this representation to inject the wave with a toroidal angle with respect to the magnetic field direction, a situation typical of ECCD. The red dashed curve shows the cold EC resonance.

Introduction

As discussed in (Galvao, 2020), there are a number of configurations for confining a fusion plasma by a magnetic field. Presently, the highest values of the triple product $nT\tau_E$, the figure of merit for achieving a self-heated ('burning') plasma introduced in (Wade, 2020), have been reached in the tokamak configuration. Here, n is the particle number density, T the temperature and τ_E the energy confinement time. In the following, we will express T in eV, where $T(\text{eV}) = k_B T(\text{K})/q_e$, with k_B the Boltzmann constant and q_e the electron charge. As introduced in (Galvao, 2021), the tokamak is an axisymmetric toroidal configuration in which the confining helical magnetic field is produced by a combination of the toroidal component, B_ν , generated by external coils, and the poloidal component, B_{pol} , generated by a strong toroidal plasma current induced by a central transformer coil. This Chapter reviews the status of experimental tokamak research, and the achievements made towards realizing a burning plasma as the core of a future fusion power plant.

For an attractive tokamak fusion power plant, ultimately two high-level goals have to be achieved:

- Producing enough fusion power P_{fus} to become an economically attractive plant. This condition can be characterized by the ratio of fusion power to auxiliary heating power P_{AUX} , $Q = P_{fus}/P_{AUX}$. Assuming that P_{AUX} is the dominant internal electricity consumer, and inserting typical efficiencies one arrives at values of the order of order $Q > 50$ to achieve acceptable recirculating electrical power below 10% of the generated power (Zohm, 2019).
- Achieving a pulse length that allows for high duty cycle, approaching steady-state operation. Since the sustainment of plasma current by the transformer is limited by the flux swing of the primary coil, this can only be achieved by relying heavily on non-inductive current driven by auxiliary systems (Dumont, 2021) or making use of the intrinsic (thermoelectric) bootstrap current introduced in (Sarazin, 2021).

To achieve these goals, one has to obtain the necessary $nT\tau_E$ for long enough pulse length τ_{pulse} . Two obvious areas of tokamak physics related to this are the energy confinement that sets the value of τ_E , and magnetohydrodynamic (MHD) stability that limits the achievable value of the kinetic pressure $p = nT$, or when ratioed against the magnetic field pressure, $B^2/(2\mu_0)$, the value of the normalized plasma pressure $\beta = 2\mu_0 < p > / B^2$. The experimental progress in these two areas is described in Sections "Energy confinement" and "Stability," respectively. Another important area, not explicitly appearing in the triple product, is the exhaust of power and particles: a substantial heat flux from the plasma impinges on the first wall, and in Section "Exhaust" we discuss the envisaged solution to this problem in a tokamak, including exhaust of the fusion 'ash,' i.e. the He particles after they have heated the plasma by collisional slowing-down.

Having presented the different physics elements, we discuss in Section "Tokamak scenarios" how to integrate these into what is called a 'tokamak operation scenario,' i.e. a recipe to operate a tokamak in a way that optimizes Q and/or τ_{pulse} . This optimization mainly relies on tailoring the radial profiles of pressure and toroidal current density, partly by sophisticated feedback control, but also relying on nonlinear self-organization. It will be shown that the strategies to optimize the two parameters are different, so that an ultimate tokamak scenario satisfying both requirements will have to rely on a trade-off between the two.

Energy confinement

Already the very first tokamak experiments in Russia showed, compared to other experiments at that time, impressive confinement qualities, with central electron temperatures reaching 1 keV. With more tokamak facilities being built also in the USA and Europe, the confinement time could be scaled with the device parameters, and a first analysis yielded a proportionality of τ_E with electron density n_e and poloidal cross section a^2 (a being the minor plasma radius). However, with purely 'ohmic' heating, i.e. the Joule heating due to the plasma current I_p driven by the transformer loop voltage, the range of achievable temperatures was very limited since the plasma resistivity drops as $T^{-3/2}$, i.e. the heating becomes ineffective at higher temperatures. This problem was overcome

with the application of auxiliary heating power P_{AUX} (Dumont, 2021), and the decoupling of I_p and P_{AUX} allowed to establish the basic dependencies of energy confinement in tokamaks in the form

$$\tau_{E,scal}[s] = c \times I_p^{\alpha_I} a^{\alpha_a} R_0^{\alpha_R} P_{tot}^{\alpha_P} B_t^{\alpha_B} n_e^{\alpha_n} K^{\alpha_K} [MA, m, m, MW, T, 10^{20} m^{-3}] \quad (1)$$

with c a fitting constant, R_0 the plasma major radius, P_{tot} the total heating power and κ the elongation of the poloidal plasma cross section. Exponents are shown in Table 1 for the L-mode (Yushmanov et al., 1990) and H-mode (ITER Physics Basis, 1999) confinement regimes introduced in (Jenko, 2021). The H-mode scaling is often used to normalize the experimentally determined confinement time $\tau_{E,exp}$ through the H-factor $H = \tau_{E,exp}/\tau_{E,scal}$.

While the exact values of the exponents differ between the two scalings, one can conclude that both show a nearly linear scaling with plasma current, while the dependence on toroidal field is much weaker. In addition, τ_E is roughly proportional to the plasma cross-section (a and R_0 are coupled via the aspect ratio which does not vary too much in the data sets). Most importantly, though, τ_E decreases strongly with heating power, meaning that plasma energy will only increase with $P^{(1-\alpha_P)}$. This ‘power degradation,’ which only emerged when experiments with additional heating could be conducted, proved to be a major obstacle for progress towards reactor relevant $nT\tau_E$ values, which are in the range of $10^{20} m^{-3}$, 10 keV and 5 s.

Comparing to collisional (‘neoclassical’) transport theory, neither absolute values nor the scaling with field and power are consistent, which is a clear indication that turbulent processes dominate the transport properties perpendicular to the magnetic field. Hence, studies of turbulent transport have been a major topic on tokamak experiments worldwide in the last two decades. An important fundamental finding was that of ‘profile stiffness,’ i.e. an invariance of the shape of the temperature profiles under large variation of external control parameters. The left plot in Fig. 1 shows this for the electron temperature on the ASDEX Upgrade tokamak: when plotted on a logarithmic scale, the profiles are just shifted, i.e. multiplied by a constant factor (Suttrop et al., 1997b).

Together with theoretical considerations, this has been connected to a fundamental property of the underlying turbulence, namely a threshold behavior of the heat conductivity with respect to the temperature gradient. This could be verified in several tokamaks worldwide using sophisticated heating scans, and an example is shown in the right part of Fig. 1, where the strongly nonlinear dependence of the heat flux q on the temperature gradient length is evident. This universal behavior has also been confirmed by measuring the radial propagation of heat waves generated by modulated localized heating of the plasma (Ryter et al., 2005). Similar findings hold for the ion temperature profiles (Mantica et al., 2009), while the density profiles have been found to exhibit a larger variation. This is due to the existence of an inward ‘pinch’ that leads to a peaking of density profiles even though the particle source is usually located in the periphery (Angioni et al., 2003).

Table 1 Exponents of the confinement scalings for L- and H-mode regimes according to Eq. (1).

	C	α_I	α_a	α_R	α_P	α_B	α_n	α_K
L-mode	0.048	0.85	0.3	1.2	−0.5	0.2	0.1	0.5
H-mode	0.0562	0.93	0.58	1.39	−0.69	0.15	0.4	0.78

Fig. 1 Logarithmic plot of electron temperature profiles showing self-similarity (left). This self-similarity, also dubbed ‘profile stiffness,’ is due to the nonlinear threshold dependence of the electron heat flux per particle q_e/n_e on the normalized temperature gradient R/L_{Te} where $L_{Te} = T_e/\nabla T_e$ shown on the right. From (Left) Suttrop W et al. (1997b). Identification of plasma-edge-related operational regime boundaries and the effect of edge instability on confinement in ASDEX Upgrade. *Plasma Physics and Controlled Fusion* 39: 2051, Fig. 8, © IOP Publishing, Reproduced with permission. All rights reserved. (Right) Ryter F et al. (2005) Experimental study of trapped-electron-mode properties in tokamaks: threshold and stabilization by collisions. *Physical Review Letters* 95: 085001, Fig. 1.

While the stiff nature of the temperature profiles would indicate that profiles always have a canonical shape, it has been found in many tokamaks that there can be deviations due to a change in turbulence behavior. Such a modification of turbulence can e.g. be induced by a variation of the ratio of electron to ion temperature or by interaction of turbulence with suprathermal plasma particles. The most prominent effect, however, is the reduction or even suppression of turbulence by sheared rotation that can strongly decrease the radial correlation length of turbulent eddies. It was discovered in the ASDEX tokamak (Wagner et al., 1982) that in the tokamak edge, above a certain heating power threshold, a strong increase of the temperature and density profiles can occur, and an ‘edge pedestal’ develops, leading to an increase in temperature and density over the whole plasma radius. In this H(High Confinement) mode, the energy confinement time is roughly doubled with respect to the L(Low Confinement) mode conditions without a pedestal. The reason for the strong reduction of transport in this ‘edge transport barrier’ region was found to be a narrow layer of sheared rotation (Burrell et al., 1990). Subsequently, transport barriers could also be created in the plasma core, dubbed ‘internal transport barrier’ (ITB), and also their occurrence could be linked to a region of strongly sheared rotation, although here, also the magnetic shear plays a role (Levinton et al., 1995). Fig. 2 shows kinetic profiles of a discharge in the DIII-D tokamak exhibiting simultaneously transport barriers in the plasma edge and the core, together with the profile of the radial electric field E_r . The latter is connected to the plasma rotation and has been shown to be the key quantity for turbulence suppression (see also Jenko, 2020).

While the experimental characterization of the H-mode edge transport barrier has progressed significantly over the years, a quantitative theory for the heating power threshold to access H-mode, P_{LH} , has not yet been established. The threshold power is hence usually described in a scaling derived from a multi-device database (Martin et al., 2008), similar to that shown for energy confinement in Eq. (1).

Stability

The theory of MHD stability of magnetically confined fusion plasmas has been outlined in (Lao, 2020). According to theory, the fastest growing instabilities are those of ideal MHD, where the perturbations conserve the topology of the plasma and the growth can be on the so-called Alfvén time scale. This time scale is given by the inertia of the plasma as it moves with the magnetic field, and, due to the small mass density of a fusion plasma, is quite fast in tokamaks, on the order of 10s of μ s. Experimentally, the predicted stability limits are in good agreement with the theoretical prediction, especially if the presence of electrically conducting structures, which can slow down the growth due to eddy currents induced in them, is accounted for in the analysis. If a significant population of suprathermal particles is present in the plasma, these can also affect MHD stability via kinetic effects.

Fig. 2 Occurrence of transport barriers in the DIII-D tokamak: an internal transport barrier develops in the ion temperature profile T_i (left) around normalized radius $\rho = 0.4$ for both cases shown, in the ‘QDB’ (Quiescent Double Barrier) H-mode, also an edge transport barrier can be seen close to $\rho = 1.0$. The right graph shows that the barriers coincide with regions of strong shear in the radial electric field E_r . From Burrell KH et al. (2001) Quiescent double barrier high-confinement mode plasmas in the DIII-D tokamak. *Physics of Plasmas* 8: 2153, Fig. 10A and C.

For purely current driven modes, a kinking of the plasma columns (so-called ideal kink mode) resonant on a major rational surface (i.e. $m/n = q$, with m and n the poloidal and toroidal mode number and q the safety factor, as defined in [Lao, 2021](#)) close to the plasma edge is observed for significant edge current gradients. For tokamak operation, this limits the current ramp rate since, due to current diffusion, a fast ramp rate will create a large edge current, but in practice, current ramps are slow enough to avoid this problem. More important is the limit on the total current, expressed by the edge safety factor $q_{edge} \sim 1/I_p$. While theory predicts unconditional instability below $q_{edge} = 1$, the occurrence of a ($m = 2$, $n = 1$) kink mode practically already limits the operation to $q_{edge} > 2$ unless active control of the kink mode by external coils counteracting the kink field is applied ([Zanca et al., 2012](#)).

The situation becomes more complex when the destabilization by the kinetic pressure gradient is added. Increasing the averaged normalized plasma pressure β will ultimately also lead to the onset of a kink instability. Experimentally, the ideal β -limit in tokamaks largely follows the so-called Troyon scaling ([Troyon et al., 1984](#))

$$\beta_{max} [\%] = const. I_p / (aB) \text{ [MA, m, T]} \quad (2)$$

with the exact value of the constant depending on details of the current and pressure profiles as well as the shape of the poloidal cross-section. As a general rule, a broader current profile will be less stable, which has been taken into account by including the internal inductance of the plasma column, $\mathcal{L}_i$, into the scaling. Normalizing β to the Troyon scaling, one finds as a rule of thumb for the maximum ‘normalized beta,’ $\beta_N = \beta / (I_p / (aB))$ the expression $\beta_{N,max} \sim 4 \mathcal{L}_i$. In [Fig. 3](#), data from the DIII-D tokamak are shown versus the two scalings, indicating that the Troyon limit is a very good overall description of the ideal β -limit, especially if the $\mathcal{L}_i$ correction is taken into account ([Taylor et al., 1994](#)).

Since the maximum achievable β is directly linked to the maximum fusion power ($P_{fus} \sim \beta^2 B^4 R^3$ in the optimum temperature range), it is important to optimize its value. Experiments have clearly demonstrated that, in line with theoretical predictions, the shape of the poloidal cross-section can significantly increase the β -limit ($\beta_{N,max} = 2.8$ for a circular cross section, while the values shown in [Fig. 3](#), left, exceed this value due to shaping). Also, the presence of a large fraction of suprathermal ions has been shown to have a significant effect on stability. Finally, adding a conducting wall close to the plasma boundary counteracts the growth of an instability on the timescale for the penetration of the perturbation field through the wall. For close coupling, this can dominate the instability growth and the ideal kink turns into a resistive wall mode (RWM, [Bondeson and Ward, 1994](#)) that grows on the wall resistive penetration time scale. Experimentally, this allows the growth to be slowed down to a value that makes it accessible for direct feedback control by magnetic coils that counteract the growing perturbation ([Sabbagh et al., 2002](#)).

While the Troyon limit is a limit to the global (volume averaged) β , MHD instabilities can also be driven locally by steep gradients. The most prominent example is the Edge Localized Mode (ELM, [Zohm, 1995](#)), an instability driven by the large gradients of pressure and current in the H-mode edge transport barrier introduced in the previous section. Here, the current gradient is mainly due to the bootstrap current driven by the pressure gradient (discussed in Section “Tokamak scenarios”). ELMs manifest themselves as a relaxation instability of the plasma edge, periodically removing the gradients by ejection of particles and energy during the instability, followed by a phase in which the gradients recover until the next ELM becomes unstable. While the associated ELM energy loss decreases the energy confinement time, the ejection of particles provides an effective control of the particle inventory, and without ELMs, H-mode plasmas tend to accumulate impurities up to an intolerable level. However, extrapolating the divertor heat loads due to ELM events to fusion reactors shows that ELMs will have to be mitigated or fully suppressed. This is possible by

Fig. 3 Experimentally obtained values of toroidal beta β_T in selected DIII-D discharges versus the Troyon scaling factor I/aB (left). An improvement of the ordering of points is achieved if the internal inductance $\mathcal{L}_i$ is explicitly accounted for in the scaling (right). From Taylor TS et al. (1994) *Experimental achievement of toroidal beta beyond that predicted by ‘Troyon’ scaling*. General Atomics Lab Report, GA-A21821, Fig. 3.

applying 3-D resonant magnetic perturbations (Evans et al., 2008) to the plasma edge or by invoking other, more benign, transport mechanisms that keep the pedestal gradients below the ELM onset level. One candidate for such an operational regime is the Quiescent H-mode regime (Burrell et al., 2001), in which ELMs are replaced by a saturated MHD mode that distorts the plasma edge and leads to additional transport. This is an active field of research, and optimization of the plasma edge is still ongoing at the time of writing of this article.

The instabilities discussed so far are all described by ideal MHD, but another class of MHD instabilities affecting tokamak operation exists, namely that of ‘resistive MHD,’ i.e. finite electrical conductivity giving rise to reconnection of magnetic field lines and change of magnetic topology. Such ‘tearing modes’ manifest themselves in tokamak discharges in the form of magnetic islands that locally flatten the kinetic profiles, leading to a loss of plasma stored energy. For Neoclassical Tearing Modes (NTMs), the main drive is the local loss of bootstrap current due to the flattened pressure profile within the island, which reinforces the magnetic perturbation, increasing the island width. NTMs hence constitute a resistive β -limit that is often observed in experiments at β_N values well below the ideal limit (Sauter et al., 1997).

Even at very low β , tearing modes can still be driven unstable if the current density gradients are too strong. Most prominently, this occurs at the ‘density limit’: with excessive fueling of the plasma, the edge region can cool down rapidly due to a thermal instability such that the current is expelled from this region (remember that the electrical conductivity is proportional to $T^{3/2}$ Sarazin, 2020), which triggers current driven tearing modes. In the presence of multiple tearing modes, the magnetic field lines can become stochastic, leading to a rapid global loss of plasma energy (‘thermal quench’). During this event, the temperature falls to such low values across the whole plasma that the plasma current can no longer be sustained by the transformer and decays resistively on the timescale of ~ 10 ms in present day experiments. The main tearing modes observed during such a ‘disruption’ are of low order, i.e. ($m = 2, n = 1$) and ($m = 3, n = 1$) (Suttrop et al., 1997a). While no generally accepted first-principles description of the tokamak density limit exists, a multi-device study showed that it can be described by the empirical ‘Greenwald limit’ (Greenwald et al., 1988)

$$n_{e,max} [10^{20} \text{ m}^{-3}] = I_p / (\pi a^2) [\text{MA}, \text{m}] \quad (3)$$

While (3) was originally derived for the average density, it is meanwhile established it this is a limitation to the achievable edge density, so that in discharges with peaked density profiles, the central density can easily exceed the value given by (3).

Disruptions pose a threat to the integrity of device components that can experience large pulsed heat loads and $j \times B$ forces due to the current density j induced in components by the changing magnetic flux (Wesson et al., 1989). An example is shown in Fig. 4. Disruptions can not only be triggered by the density limit, but also by excessive radiation loss due to impurities entering the plasma (e.g. wall fragments) or even by NTMs induced by the resistive β -limit. Avoiding disruptions, or mitigating their consequences, is of crucial importance for any future reactor-grade tokamak. For example, magnetic islands can be removed by locally driving currents in the islands, usually by Electron Cyclotron Current Drive (ECCD, Zohm et al., 1999), which can drive current in a very localized radial region (Dumont, 2021). Heat loads and forces are effectively reduced by injecting large amounts of fuel gas or impurities that dissipate the available free energy isotropically through electromagnetic radiation. A related problem is the occurrence of ‘runaway’ electrons during the current quench, i.e. a population of electrons that acquires such high energy that collisional drag can no longer balance the acceleration in the induced toroidal electric field (which is large due to the changing plasma current during a disruption). These can pose an additional threat to future devices and mitigation or avoidance techniques are actively studied.

Fig. 4 JET density limit disruption (left): after the thermal quench, in which the electron temperature falls drastically, the plasma current cannot be sustained any longer in spite of the rising loop voltage. Example of a thermal quench through interacting magnetic islands during a disruption in ASDEX Upgrade, visualized by lines of equal temperature (right). Due to the toroidal rotation of the plasma, the toroidal angle is equivalent to time for stationary conditions up to 1.72 s, when the disruption happens. From (Left) Wesson JA et al. (1989) Disruptions in JET. *Nuclear Fusion* 29: 641, Fig. 29. (Right) Suttrop W et al. (1997a) Tearing Mode formation and radiative edge cooling prior to density limit disruptions in ASDEX Upgrade. *Nuclear Fusion* 37: 119, Fig. 4.

Three other types of MHD instabilities are common in tokamak discharges:

- The ‘sawtooth’ instability (Von Goeler and Sauthoff, 1974), which is a periodic resistive relaxation of the plasma core due to (1,1) kink instability in a region with $q < 1$ in the plasma center, mainly driven by the current density gradient. The main effect of sawteeth is to limit the central current density and to periodically redistribute energy and particles across the $q = 1$ surface.
- The ‘error-field locked mode’ (La Haye et al., 1992) which is a magnetic island occurring preferentially at low plasma density due to the plasma response to an externally applied helical magnetic perturbation. The perturbation can also be due to imperfections of the field coil system (even small perturbations are resonantly amplified) and since it is usually an ($m = 2, n = 1$) island, may lead to a disruption.
- ‘Fast particle modes’ (Gorelenkov and Sharapov, 2021) which are (often ideal MHD stable) plasma modes excited by a population of suprathermal particles, which in turn can be redistributed or expelled by the modes. These modes are especially important for future burning plasma experiments where fast particles from the fusion reaction are expected to be the main plasma heating mechanism.

Exhaust

While the preceding sections have focused on the performance of the plasma core, it is equally important for a future reactor to exhaust the heat and particles which are inevitably lost from the confined plasma due to radial transport. While the first tokamaks used material limiters that defined the last closed flux surface, it is now established to use a divertor configuration in which the last closed flux surface is defined magnetically by a separatrix and the field lines on the surrounding surfaces, the Scrape-Off-Layer (SOL), end on the divertor target plates, as shown in Fig. 5.

First experiments in divertor geometry showed that due to the avoidance of direct wall contact, the impurity concentration in the plasma could be kept lower than by using a limiter. Another important finding was that a substantial difference in neutral gas pressure between the main chamber and the divertor region can be maintained, easing the pumping of fuel and impurities from the latter region. For example, it was shown that the core He content could be effectively diminished by pumping He from the divertor in DIII-D, with the residence time of He in the system being of order 5–10 times the energy confinement time (Wade et al., 1995), which meets the requirements for He ash removal from future reactors (Reiter et al., 1990).

Concerning heat exhaust, the divertor offers the possibility to decouple the plasma temperature of the last closed flux surface from that at the target plate, allowing a hot plasma edge while the divertor plasma has a substantially lower temperature, which strongly decreases the sputtering of target plate material by the impinging plasma particles. This is possible since the ‘connection length’ between the main chamber and the target plate along magnetic field lines can be substantial, of order $2\pi qR$, i.e. tens of meters in present day experiments, and the temperature falls in the direction of the divertor target due to the finite parallel heat conductivity. Since the pressure must be constant along field lines, the density increases accordingly. Experimentally, different divertor operating regimes are identified, usually as the plasma density is increased:

- ‘Sheath limited’: at low density, there is hardly a drop in temperature along field lines and the target plasma temperature is given by the capability of the sheath at the target to transmit energy.
- ‘High recycling’: at higher density, the target temperature can drop substantially into the 5 eV range. The ion flux to the target increases substantially due to recycling neutrals.
- ‘Detached’: at even higher density, the plasma recombines before reaching the target plate, and the drop in plasma pressure is balanced by the neutral pressure in front of the plate.

Fig. 5 Limiter (left) and separatrix (right) geometry to define the last closed flux surface (shown in red).

These regimes are illustrated in Fig. 6, which shows SOL pressure and temperature profiles in the main chamber midplane of the Alcator C-mod tokamak, compared to those at the divertor target plate. Note that the pressure is multiplied by a factor of 2 to account for the dynamic pressure of the plasma flow that reaches the plate at sound speed.

It can also be seen in Fig. 6 that the perpendicular width of the part of the SOL in which the power is conducted can be very narrow, of the order of a few mm in present day experiments. A multi-device scaling for attached divertor regimes shows that this width scales inversely with the poloidal magnetic field, and hence is not expected to increase with device size (Eich et al., 2011). For future reactor grade plasmas, the unmitigated power load on the divertor target plates thus extrapolates to values well beyond the steady state component limit (which is roughly 10 MW/m² using present-day technology). It will hence be crucial to achieve detachment in these devices, at least in the radial part of the SOL where the heat flux would exceed this limit.

Depending on the magnitude of the power flux into the SOL, the detached state may not be achievable at the tokamak's operating density. In this case, it has been shown that adding 'seed' impurities into the divertor plasma that increase the radiative losses by line radiation can ease the access to detachment. Likewise, impurity seeding in the main plasma has been applied to reduce the power flux across the separatrix. Fig. 7 shows an example where a simultaneous control of divertor and main chamber radiation has been feedback controlled by injecting two different impurity species (N for the divertor and Ar for the main chamber).

Fig. 6 Comparison of main chamber midplane ('upstream') and divertor temperature T_e and pressure nT_e profiles in the Scrape-Off-Layer of the Alcator C-Mod tokamak. In the sheath limited regime (left), temperature and pressure profiles are similar at both locations, while in the high recycling regime (middle plots), the temperature is reduced at constant pressure. In the detached regime (right), also the pressure is reduced substantially (La Bombard et al., 1995). From La Bombard B et al. (1995) Scaling and transport analysis of divertor conditions on the Alcator C-Mod tokamak. *Physics of Plasmas* 2: 2242, Fig. 5.

Fig. 7 Double feedback control of divertor and main chamber radiation (labelled $P_{\text{rad,div}}$ and $P_{\text{rad,main}}$ in the upper left panel) using N and Ar seeding, respectively (gas fluxes shown in the upper right panel) in ASDEX Upgrade (Kallenbach et al., 2012). Despite the high heating power of ~ 20 MW, the peak heat flux on the divertor target is only 4 MW/m² (lower right panel) and plasma performance in terms of normalized confinement H and pressure β_N is quite high (lower left panel). From Kallenbach A et al. (2012) Optimized tokamak power exhaust with double radiative feedback in ASDEX Upgrade. *Nuclear Fusion* 52: 122003, Fig. 4.

While these methods work well in order to control the heat flux on the target plates, they are limited by the maximum impurity fraction in the plasma that still allows stationary burn of the fusion plasma (Reiter et al., 1990). In addition, the impurity species have to be selected carefully such that the main radiation losses come from the plasma periphery. Usually, noble gases are preferred since they do not undergo chemical reactions with fuel or wall material, which could lead to trapping of impurities or even of the Tritium fuel.

Another topic related to exhaust is the choice of wall material. Due to erosion, some wall material always contaminates the plasma, leading to additional radiation losses and fuel dilution. For low- Z materials, where Z is the charge number of the nucleus, the allowable concentration in a reactor would be of the order of few percent, while for high- Z , the concentration must be kept of the order of some 10^{-5} . For this reason, tokamaks preferably operated with C wall in the 1990s. Extrapolating to a reactor, it became clear that the level of erosion and the trapping of fuel in hydrocarbons would be unacceptable, even for very low divertor plasma temperatures, since chemical erosion is still present with C first wall elements. For this reason, tokamak operation with all-metal wall (Mo in the case of Alcator C-Mod, W for ASDEX Upgrade and W-Be for JET) has been studied in detail. It is generally found that the H-mode operational space is restricted with respect to operation with a C-wall: in order to avoid excessive influx of wall material, plasmas have to be operated with higher fueling gas flux in order to keep the ELM frequency high enough for flushing impurities from the edge. Such a high fueling rate decreases H-mode confinement quality, which is now understood as an effect of reduced edge pedestal stability (Dunne et al., 2017). This has to be taken into account when extrapolating to future reactors that are supposed to operate with metal wall.

Tokamak scenarios

While the previous sections have described experimental progress in the areas of core confinement, stability and exhaust, we now discuss how to integrate these elements into a coherent plasma operation scenario ('tokamak scenario'). In order to achieve a burning fusion plasma, the triple product $nT\tau_E$ has to attain a certain value given by the Lawson criterion (Wade, 2021). Since this criterion has a minimum at $T \sim 20$ keV, it mainly means operating at high density and long energy confinement time. According to (1), increasing the confinement time can most prominently be achieved by increasing plasma current and device size, with the plasma current, for given device size, being limited by the low- q kink limit. Increasing the plasma current will also raise the achievable density according to (3). In addition, the product nT has to be kept below the pressure limit described by (3), which also increases with plasma current. Plasma scenarios that aim at optimizing the value of $nT\tau_E$ are hence usually run at the highest field the device can produce, with plasma current as high as possible, just avoiding the low- q limit. This recipe was used successfully in the D-T experiments in TFTR (Hawryluk, 1998) and JET (Keilhacker et al., 1999), which produced record values of fusion power of up to 16.1 MW in JET, at a power amplification of $Q = 0.67$. This enabled proof-of-principle experiments demonstrating plasma heating by the fusion-born α -particles (Thomas et al., 1998). Fig. 8 shows these results. In TFTR D-T experiments, Alfvénic Eigenmodes, driven by the α -particles were also clearly identified.

In addition to the D-T experiments in TFTR and JET, performance was also maximized at low q in deuterium discharges in JT-60U, leading to a record triple product of $nT\tau_E = 1.53 \times 10^{21}$ keV s m $^{-3}$, i.e. roughly a factor of 3 short of the numbers needed for a commercial fusion power plant mentioned in Section "Stability." The JT-60U tokamak also holds the record for the highest ion temperature achieved at $T_i \sim 45$ keV (Ishida et al., 1997).

Fig. 8 Record fusion power ($P_{fus} = 16.1$ MW) discharge in JET (left) and proof of α -heating by varying the isotope mix (right, Tritium-percentage given in brackets). The highest central electron temperature $T_e(0)$ is indeed achieved with a roughly equal percentage of deuterium and tritium. From (Left): Keilhacker M et al. (1999) High fusion performance from deuterium-tritium plasmas in JET. *Nuclear Fusion* 39: 209, Fig 3. (Right) Thomas PR et al. (1998) Observation of alpha heating in JET DT plasmas. *Physical Review Letters* 80: 5548, Fig. 3.

The experiments described above were optimized in order to transiently achieve record values (note that the high performance phase of the record D-T discharge shown in Fig. 8 was terminated by an MHD instability). For future fusion reactors, it is essential that the fusion power can be generated quasi-continuously, i.e. the pulse length τ_{pulse} should be maximized as well. For tokamaks, this is a non-trivial task since the plasma current is usually maintained against the (small but finite) electrical resistivity of the plasma by slowly ramping down the current in the central solenoid coil until the flux swing of the coil is exhausted. In order to prolong the pulse length, the current hence has to be driven non-inductively. Two main methods exist for this:

- Current drive by external heating systems: as described in (Dumont, 2021), both neutral beam and RF heating methods have the possibility to generate toroidal plasma current.
- Current generated by the bootstrap effect: as described in (Sarazin, 2021), a radial pressure gradient in a toroidal confinement system drives a toroidal current by a thermoelectric effect.

An extrapolation of the current drive efficiency of external systems shows that in reactor-grade tokamaks, it will not be possible to drive the whole plasma current externally with reasonable power consumption. Experiments have hence focused on maximizing the fraction of bootstrap current f_{bs} . Since the bootstrap current is proportional to $\nabla p/B_{pol}$, the bootstrap fraction can be expressed as

$$f_{bs} = \frac{I_{bs}}{I_p} = c_{bs} \sqrt{\frac{a}{R}} \beta_{pol} \propto q \sqrt{\frac{R}{a}} \beta_N \quad (4)$$

with c_{bs} being a constant whose value depends on the shape of the current and pressure profiles, where the definition of β_{pol} is the same as given above for the toroidal beta, β_t , but using the poloidal magnetic field as normalization. This dependence has been verified experimentally in a number of tokamaks (Kikuchi and Azumi, 1995). While this means that, similar to optimization of the triple product, high β operation is favorable, the bootstrap fraction is maximized by increasing q , i.e. decreasing the plasma current, opposite to the strategy for optimizing the triple product. Hence, for long pulse or steady state (i.e. 100% non-inductive current drive) tokamaks, there needs to be a compromise between fusion performance and pulse length. These scenarios, known as ‘advanced tokamak scenario’ aim at optimizing the current and pressure profiles such that c_{bs} is maximized within the MHD stability limits. Here, a critical problem is the alignment of the bootstrap current profile with the current profile needed to produce the desired q -profile. Fig. 9 shows an example from the JT-60 U tokamak in which the majority (80%) of the current is driven by the bootstrap current for several seconds (Ide et al., 2005).

The profiles of q and T_i shown in the right panel of Fig. 9 demonstrate the optimization strategy described above: not only is q high at the edge, meaning a relatively small plasma current, but also the q -profile shows a non-monotonic behavior (so-called reversed shear). This increases the bootstrap fraction with respect to a typical q -profile in an ohmic discharge, which would be decreasing monotonously from the edge to the center since the ohmic current density is highest there. The T_i profile exhibits an ITB (see also subsection on transport) at $\rho = 0.5$, and the large pressure gradient there creates a local maximum in the bootstrap current density, supporting the q -profile reversal.

While this route to fully non-inductive tokamak plasmas has been demonstrated in principle on several devices (including a fully self-organized discharge in TCV where the plasma current was no longer feedback controlled Sauter et al., 2001), it remains difficult so far to maintain MHD stable profiles over a longer time and to establish a confinement quality sufficient for reaching a high triple product even at lower current. In an alternative approach, the so-called ‘hybrid’ scenario, one therefore aims at operating at higher plasma current, albeit still with central q -profiles that are elevated with respect to standard ohmic profiles, but not reversed, leading to increased MHD stability limits. Due to the lower bootstrap fraction, these scenarios, as e.g. established in ASDEX Upgrade (Sips et al., 2002) and DIII-D (Luce et al., 2003), might not extrapolate to true steady state, but could offer at least greatly enhanced τ_{pulse} .

Fig. 9 Non-inductive discharge in JT-60U: time traces of plasma beta (feedback controlled by NBI heating), confinement quality H_{89} and loop voltage V_{loop} (left). The right panel shows the profiles of safety factor q and ion temperature T_i , where an internal transport barrier can be recognized at normalized radius $\rho \sim 0.5$. From Ide S et al. (2005) Overview of JT-60U progress towards steady state advanced tokamak. *Nuclear Fusion* 45: S05, Fig. 8.

It is important to mention that long pulse or steady state tokamak discharges also pose significant technological challenges in terms of steady state removal of heat and particles as well as reliability of the individual systems needed for tokamak operation. This is mainly the domain of tokamak devices with a superconducting coil set, allowing the study of long pulse physics and technology. In the Tore Supra tokamak, more than a Gigajoule of heating energy was supplied in a 6 min long discharge (Van Houtte et al., 2004), where steady state was achieved by driving the current externally with Lower Hybrid waves in a low density L-mode plasma. More recently, very long H-mode discharges were demonstrated in KSTAR (70 s Oh et al., 2018) and EAST (100 s Gong et al., 2019).

Finally, it is worth pointing out that the development of stable integrated tokamak operation scenarios relies strongly on feedback control of the plasma parameters (Lister et al., 1999). While the first tokamak experiments relied purely on feedforward optimization of the discharge evolution, a major breakthrough was obtained by active control of plasma current and position inside the vacuum vessel using pick-up coils and flux loops as sensors and the poloidal magnetic field coils as actuators in the 1970s. This was extended to magnetic feedback control of the shape of the plasma cross-section in the 1980s, and the magnetic configuration is routinely controlled in all tokamaks worldwide since then. However, in future fusion reactors, it will be necessary to also control the kinetic quantities plasma temperature and density, and to some extent also their radial profiles, in order to guarantee a stable operational point with reliable constant fusion power output. Since the 2000s, more and more sophisticated control loops have hence been introduced for kinetic control, and examples can be found in the beta control shown in Fig. 9 or the radiation control shown in Fig. 7. These rely on additional sensors for the controlled quantities, and hence have profited substantially from the development of sophisticated plasma diagnostics, which are also used for physics studies. Typical actuators are the heating and fueling systems described in this chapter as well as in (Dumont, 2021).

The integrated control of tokamak scenarios has hence become a MIMO (Multiple Input–Multiple Output) problem, which is also due to the nonlinear relation between the different control quantities, and thus requires sophisticated control strategies beyond classical linear control schemes. For future fusion reactors, one has to take into account that available sensors will be limited due to the harsh environment involving a significant neutron flux. Concerning actuators, the superconducting poloidal field coils with large stored magnetic energy imply a relatively slow reaction, and the power delivered by the heating and current drive systems will have to be small compared to the intrinsic α -heating power in an efficient reactor. On the other hand, a key aspect which will be different from the present experimental devices is that a fusion reactor will have one well-defined operational point and control can be optimized around it.

Summary

Tokamak experiments have made major progress in achieving plasma parameters close to those required for a fusion reactor, and, together with theory, the fundamental understanding of the underlying fusion plasma physics has advanced to a state that has allowed to design and construct the ITER device, which is set to demonstrate generation of fusion power at 10 times the value of power injected into the plasma.

Table 2 gives an overview of significant past and current tokamak devices around the world, including also the ITER device parameters.

Table 2 Parameters of significant past and current tokamak devices, including ITER.

Device name	Operation period	Country	Major radius [m]	Minor radius [m]	Toroidal field [T]	Plasma current [MA]	Divertor configuration	Additional heating [MW]			
								NBI	ICRH	LHRH	ECRH

Glossary

Ballooning mode One of the MHD instabilities driven by pressure gradients. The ballooning mode is localized on the outboard side of the torus where the magnetic field is weak and characterized by short wavelengths.

Bootstrap current In the presence of a pressure gradient in a toroidal plasma, the characteristic motion of charged particles trapped in a magnetic mirror due to toroidicity can produce a net toroidal current. This spontaneous non-inductive current is referred to as a bootstrap current. In stellarators, particles trapped in a helical magnetic field ripple play a complementary role to particles trapped in a toroidal ripple.

Electron/ion root In an axisymmetric system like a tokamak, fluxes of charged particles are intrinsically ambipolar due to collisional momentum conservation. Therefore, particle fluxes do not depend on the ambipolar electric field in tokamaks. In contrast, particle fluxes explicitly depend on the ambipolar electric field in stellarators due to asymmetry. The condition of charge neutrality requires a balance between electron flux and ion flux. A specific ambipolar radial electric field is given as a solution, i.e. a root, of this balance equation. Since this balance equation is usually non-linear with regards to the radial electric field, there can be multiple roots of the radial electric field. When the electron flux is predominant, the resultant positive electric field retards the electron flux, which consequently balances with the ion flux. This situation is called an electron root. The opposite case, which gives negative electric field, is called an ion root.

Helical ripple The magnetic field strength changes along the magnetic field lines in a toroidal confinement configuration. Primary modulation is due to the excursion of the magnetic field line between the inboard side with strong toroidal magnetic field and the outboard side with weak toroidal magnetic field of the torus. In addition, the magnetic field in stellarators is modulated by higher order harmonics due to helical coils or modular coils. This modulation is called a “helical ripple.” The change of magnetic field strength along the magnetic field line produces a “mirror trap” of charged particles. The characteristic motion of these trapped particles greatly influences transport in plasmas. Therefore, transport in stellarators is much more complicated due to a helical ripple than in tokamaks.

Interchange mode One of the MHD instabilities driven by the pressure gradient like a ballooning mode. In contrast to a ballooning mode, an interchange mode has global structure with a long wavelength. Stability against the interchange mode is violated, in particular, by magnetic hill.

Kink mode One of the MHD instabilities driven by the gradient of plasma current density. The flux tube undergoes a deformation without breaking (“tearing”) and reconnection of the magnetic field lines.

Local island divertor The last closed surface of the magnetic field is defined by the separatrix and the magnetic field lines change from a closed topology to an open topology across the separatrix. This open topology can be configured into

a “divertor” configuration. A local island divertor uses the separatrix of a magnetic “island” intentionally generated in the plasma edge by external application of resonant magnetic perturbations. A “scraper” structure is inserted into the magnetic island to provide a more enclosed region and enable divertor pumping of the resultant neutral particles.

Magnetic island The confining magnetic field of the plasma ideally forms a set of concentric nested magnetic cages like a matryoshka doll. When breaking and reconnection of magnetic field lines takes place, a magnetic cage (so-called flux tube) isolated from the rest of space can be formed. Since this topology looks like a crescent-shaped island on the poloidal cross-section, it is called a “magnetic island.”

Magnetic well/magnetic hill The plasma confined by the magnetic field prefers to expand towards a region of weaker magnetic field. When the averaged magnetic field along the magnetic field line becomes stronger in the outer confinement region than in the inner confinement region, any perturbed motion of the plasma is repelled inward and instabilities cannot develop. This situation is referred to as a “magnetic well.” In the opposite case of a “magnetic hill,” instabilities easily develop. This concept of magnetic well is an important element, together with magnetic shear, when MHD stability is discussed.

Pfirsch-Schlüter current Plasmas are diamagnetic. Since the toroidal field is predominant in toroidal confinement systems such as tokamaks and stellarators, diamagnetic currents primarily flow in the poloidal direction to reduce the toroidal field. In order to fulfill the condition that the divergence of the current is equal to zero in toroidal geometry, additional currents are driven along the magnetic field lines. This secondary current is called the Pfirsch-Schlüter current. This current deforms the magnetic flux surfaces.

Quasi-symmetry The stellarator magnetic field is intrinsically 3D and non-axisymmetric. Since the violation of toroidal symmetry degrades the confinement capability due to the drift of the particle orbits, recovery of symmetry is an essential strategy in stellarator optimization. The idea of quasi-symmetry is the establishment of a non-axisymmetric magnetic configuration where the magnetic field strength approximately depends on only one angular coordinate along the magnetic field lines. Depending on the selection of the primary angular coordinate, there are quasi-axisymmetry, quasi-helical and quasi-poloidal concepts. Quasi-isodynamics, or omnigenity, is a comprehensive approach to minimizing the drift of particle orbits.

Shafranov shift Pfirsch-Schlüter currents generated by the plasma kinetic pressure deform the magnetic flux surfaces. The primary component of the magnetic field induced by these currents is a vertical field and, therefore, the plasma column is pushed outward. This outward shift of the central axis of the plasma is called the Shafranov shift.

Tearing mode One of the MHD instabilities driven by the gradient of plasma current. Unlike a kink mode, the resistivity of the plasma plays an essential role in a tearing mode. In ideal MHD, i.e. in zero resistivity plasmas, a tearing mode does not occur. Reconnection of magnetic field lines due to resistivity produces a magnetic island and the growth of the magnetic island tears additional nested magnetic flux surfaces.

Zonal flow As a consequence of self-organization of short-wavelength turbulence in toroidal plasmas, macroscopic plasma flows in the poloidal direction are often seen. These flows are localized radially and form a multilayered structure. Inspired by the analogy to meridional flows on the earth these flows are designated zonal flows. Since zonal flows are usually sheared flows in the radial direction, they shred convective eddies of turbulence and regulate turbulent transport.

Introduction

Stellarators share the basic concept with tokamaks such that plasma is confined magnetically in a topological torus. It was pointed out in the very early stage of fusion research that a torus with simple circular magnetic field, i.e. with magnetic field lines oriented in the purely toroidal direction, is not sufficient to confine the plasma and the configuration has to have helically twisted magnetic field lines in order to avoid escape of the plasma from the magnetic bottle due to intrinsic particle drifts. Stellarators generate these twisted magnetic field lines by currents in coils outside the plasma while tokamaks generate those by currents flowing in the plasma. Eventually, stellarators are intrinsically non-axisymmetric while tokamaks are symmetric along the torus. Although the idea of stellarators was conceived by Lyman Spitzer in 1951 prior to the invention of the tokamak (Spitzer Jr., 1958a), development of this concept has fallen behind that of the tokamak in terms of the achieved performance approaching fusion conditions. This tardy progress is due to the complexity of its intrinsic 3D feature which makes theoretical modeling (Wakatanai, 1998; Boozer, 1998), as well as construction of experiment devices, difficult. However, remarkable progress in experiments and theory is revealing the stellarator’s innate advantages, such as steady-state operation (Miyamoto, 1978; Johnson, 1982; Carreras et al., 1988; Lyon et al., 1990; Lyon, 1990). As shown in Fig. 1, many experimental projects are underway and planned across the world. In particular, the present two major flagship devices; Large Helical Device (LHD in short, Toki, Japan) (Iiyoshi et al., 1990; Fujiwara et al., 1996; Motojima et al., 1999; Special Issue, 2010) and Wendelstein 7-X (W7-X in short, Greifswald, Germany) (Nührenberg et al., 1995; Wanner et al., 2001; Pedersen et al., 2017; Klincker et al., 2019) have demonstrated good performance, which is even better in some aspects than major tokamak experiments. These favorable experimental achievements, in conjunction with advances in extremely-large-scale simulation, are accelerating further optimization of the magnetic configuration and development of a stellarator fusion reactor concept.

The stellarator is a promising concept for a fusion power plant even with respect to the tokamak. The distinguishing property that there is no requirement for high currents in the plasma leads to a great advantage of stellarators in comparison to tokamaks. A

particularly important feature is the freedom from disruptive instabilities driven by plasma currents, which secures stable operation, and the absence of a requirement for current drive reduces the circulating power in a fusion power plant. While the stellarator achieved performance in terms of the “fusion triple product” (Wade, 2021) lags that of the tokamak, the importance of its complementary and alternative role to the tokamak (Stroth, 1998; Helander et al., 2012) is emphasized due to its attractiveness in both the Japanese (MEXT, 2018) and European (EUROfusion, 2018) strategies for fusion energy development. In conjunction with the ongoing progress of experiment and theory in stellarators, reactor design studies are also underway (Beidler et al., 2002; Najmabadi et al., 2008; Sagara et al., 2010) in order to exploit the potential of the stellarator fusion reactor.

Basic concept of stellarators

The basic concept of nested flux surfaces formed by twisted magnetic field lines in a topological torus is common to stellarators and tokamaks. The essential difference is that there is no net toroidal current in a stellarator plasma. Torsion of the magnetic field lines is given only by external coils in stellarators. Magnetic configuration in stellarators have wide variety according to conceptual ideas on how to twist magnetic field lines and to form nested flux surfaces. The twist of the magnetic field lines is referred to as the “rotational transform,” ι (Galvão and Canal, 2021). The rotational transform normalized by 2π , ι , is the reciprocal of the safety factor, q , which frequently appears in tokamak physics. Stellarators are defined in a broad sense as a concept of toroidal magnetic confinement by external coils and there are many diversified concepts derived from this essential principle, such as advanced stellarator, bumpy torus, classical stellarator, heliac, heliotron and torsatron in alphabetic order. The profile of the safety factor, which is the reciprocal of the rotational transform, also has a specific form depending on the concept, as shown in Fig. 2.

Fig. 3 shows the configuration of coils, the main body and the visualized magnetic field of two leading devices: Large Helical Device (LHD) heliotron and Wendelstein 7-X (W7-X) advanced stellarator. Unlike in tokamaks, nested flux surfaces exist in vacuum and therefore they are observable by detecting fluorescence light and excited low-pressure gas with electron beams (Morisaki et al., 2010; Otte et al., 2016).

The consequent outstanding advantage of stellarators is steady-state operation. High net toroidal currents in tokamaks (in the range of several MA) drive magnetohydrodynamic (MHD) instabilities (Lao et al., 2020) and these can cause abrupt termination of the plasma discharge, referred to as a “disruption.” Stellarators are free from disruptions. Even in stellarators, plasmas collapse when they approach operational limits such as those involving pressure and density. However, this collapse is benign since the magnetic bottle to confine the plasma exists in vacuum to the first order. Also sustainment of these currents in tokamaks requires auxiliary

Fig. 2 Profiles of the safety factor for various stellarators. QA relies on “bootstrap current”, which increases the rotational transform (decreases the safety factor), as seen in the change from NCSX_{vac} to NCSX_{bsc}.

Fig. 3 Configuration of coils, (a) and (d), the main bodies, (b) and (e), and visualized magnetic field surfaces in poloidal cross-section, (c) and (f) for LHD (a)–(c) and W7-X (d)–(f). Courtesy of NIFS and IPP.

input power, since currents cannot be driven inductively in steady-state. Since stellarators do not need this current drive, the recirculating power in a power plant is expected to be reduced compared with tokamaks.

It should be noted that the above mentioned advantages are produced by the three-dimensionality of stellarators. Physics tells us that symmetry corresponds to a conservation law. Translational symmetry gives rise to momentum conservation and rotational symmetry settles angular momentum conservation. Consequently, particle motion is governed by these conservation laws. This fundamental physics is seen in toroidal plasmas as well. Magnetic field strength in tokamaks does not change in toroidal angle measured on a circle about the major axis of the torus. This means tokamaks have axisymmetry (referred to as toroidal symmetry), which leads to a certain conservation law (Sarazin, 2021). In contrast, stellarators should have three-dimensionality and do not have any such symmetry. Fig. 4 compares distributions of magnetic field strength on the flux surface in a variety of stellarators and ITER. In general, the magnetic field is stronger inboard than outboard due to toroidal effects for all cases. While the case of ITER (Fig. 4a) shows toroidal symmetry, modulation specific to the various concepts is added to the cases of stellarators. The loss of toroidal symmetry gives rise to drawbacks, such as significant deviation of particle orbits from magnetic flux surfaces. Straight stellarators have helical symmetry and therefore early stellarators had large aspect ratio, i.e. R/a , the ratio of major radius of torus, R ,

Fig. 4 Distribution of magnetic field strength on the flux surface in (a) ITER, (b) QP, (c) NCSX (QA), (d) HSX (QH), (e) W7-X (QI), (f) LHD. Magnetic field strength increases from blue to red. Courtesy of Dr. Y. Suzuki.

and minor radius of cross-section of the torus, a . Although particle confinement is improved in large aspect ratio, a device becomes very large and only low pressure plasmas can retain force-balance equilibrium. An innovative approach to address the resolution of these drawbacks is recovery of symmetry (Dewar and Hudson, 1998). Although this recovery is not complete, different approaches to optimization have been proposed in a variety of “quasi-symmetry” concepts such as quasi-axisymmetry (QA) (Reiman et al., 1999; Neilson et al., 2000), quasi-helical-symmetry (QH) (Nührenberg and Zille, 1998; Boozer, 1995), quasi-polooidal-symmetry (QP) (Spong et al., 2001) and quasi-isodynamics (QI) (Gori et al., 1997; Nührenberg, 2010).

Natural history and zoology of stellarators

The original idea of stellarators was proposed by Lyman Spitzer Jr. (1914–97) in 1951 (see Fig. 5). He is also known to be a father of Hubble Space Telescope. The stellarator project, coded as Project Matterhorn S, was conducted behind the classified curtain. The project was declassified in 1958 and a milestone paper on stellarators was published in the same year (Spitzer Jr., 1958a). In this article, Spitzer implemented the basic idea of rotational transform and nested flux surfaces by two methods. One involves a twisted circle with toroidal field coils like a “figure-8” (Spitzer Jr., 1958b). It is also surprising that Spitzer already considered a pumping concept, introducing the “divertor”, and heating schemes in his very first paper (Spitzer Jr., 1958a). This figure-8 concept was abandoned shortly afterwards. The second concept described in the paper was a combination of toroidal field coils and pairs of helical coils with currents directed oppositely in adjacent helical coils. Here the number of poles of the magnetic field created by pairs of helical coils is denoted by L . The magnetic configuration of the stellarator is characterized by the toroidal field period M together with L . The classical stellarator, employing pairs of helical coils ($L = 2$ or 3) with currents in opposite directions in the adjacent coils together with toroidal field coils, was pursued in United States, USSR, Germany, United Kingdom, Japan and France (Braams and Stott, 2002). While the American initiative (Young, 1974) was converted to a tokamak at the end of the 1960s, the study of classical stellarators has progressed significantly, in particular in Germany, as the Wendelstein line (Grieger et al., 1985) (WII-A, WII-B, W7-A, W7-AS (Hirsh et al., 2008) and W7-X (Klinger et al., 2019)). Wendelstein, a mountain in Germany (not as high as the Matterhorn), means ‘a helical stone’ in German. Conceptual development led by theory has established the concept of an advanced stellarator (Wobig, 1999) employing modular coils (Chodura et al., 1981).

It is pointed out that another concept employing a pair of helical coils ($L = 2$) with currents in the same direction was envisioned by Koji Uo (1925–92) in 1958 (Uo, 1961). Unlike stellarators, this configuration named “heliotron” produces both helical and toroidal magnetic fields by a pair of helical coils without toroidal field coils. His conception originates from consideration of the magnetic field in a twisted power cable. Since then, this idea has been developed in the heliotron line (Uo, 1971) such as Heliotron C, Heliotron D, Heliotron DM, and Heliotron E (Uo, 1985; Wakatani and Sudo, 1996), leading to the present LHD project, which started operation in 1998 (Iiyoshi et al., 1999) (see Fig. 6). The same configuration with $L = 2$ or 3 helical coils with the same current direction was proposed independently as the torsatron (Gourdon et al., 1969). ATF (Murakami et al., 1991a) in USA, CHS

(Matsuoka et al., 1989) in Japan, and URAGAN-2M (Pavlichenko, 1993) in Ukraine in this category produced valuable scientific results around the 1990s.

Heliac originally stands for helical axis stellarator. The basic idea comes from nested helical “magnetic islands” developing at the rational surfaces in a current carrying plasma such as a tokamak (Furth et al., 1966). The combination of an $L = 1$ helical coil and tokamak-like toroidal field coils with centers following a helical line around the torus, as illustrated in Fig. 7, generates twisted kidney-shaped magnetic flux surfaces (Boozer et al., 1983; Harris et al., 1985). This helical configuration is highlighted by a deep “magnetic well,” which is favorable for high β operation. The H-1 heliac (Hamberger et al., 1990) was studied in Australia and has been exported to China. The present leading heliac is TJ-II (Alejaldre et al., 1990, 1999) in Spain.

The development of the natural history of stellarators is schematically shown in Fig. 7. The list of stellarator experimental devices is given in Table 1. Device size and magnetic field strength have grown together with elaborated efforts to reduce unfavorable magnetic error fields which degrade the quality of plasma confinement. Based upon scientific achievements, the line of classical stellarators has evolved into the modular coil concept, which facilitates the implementation of advanced ideas. The present flagship device of the “advanced” stellarator is W7-X, which started operation in 2015 (Pedersen et al., 2017). Optimization to restore symmetry has also been accelerated owing to progress of theory and computational capability in these years. A helically symmetric stellarator, HSX (Anderson et al., 1995, 2006), has been working in the United States and the project of a quasi-axisymmetric stellarator (NCSX) (Zarnstorff et al., 2001) was also launched in the United States, but this project was cancelled in 2008. However, a small scale device based on quasi-axisymmetry, CFQS (Xu et al., 2018), is being built in China in collaboration with Japan, and an optimization design study of a potential project, QUASAR, is progressing in the United States (Gates et al., 2017). J (Wakatani et al., 2000; Obiki et al., 2001) in Japan is a member of a family of stellarators with quasi-poloidal symmetry. LHD and W7-X are pursuing the mission of demonstrating reactor-relevant stellarator plasmas. At present, the potential to provide the basis for a fusion reactor is being explored by the leading three concepts: heliotron (LHD), advanced stellarator (W7-X) and quasi-axisymmetric stellarator.

Major findings and achievements in stellarators

Demonstration of net-current free plasmas

In principle, the stellarator magnetic field configuration produced purely by external coils has the capability to confine high-temperature plasmas. However, until the 1970s, even stellarators required ohmic heating by a plasma current, since there were no other effective schemes to initiate and heat plasmas. Therefore, the early stellarator experiments relied on the generation of net plasma currents, just as in tokamaks. From the late 1970s, auxiliary heating technology (Dumont, 2020), such as Electron Cyclotron Resonance Heating (ECRH) as well as Neutral Beam Injection (NBI), has been applied in stellarator experiments. Two innovative achievements of net-current free or current-less plasmas were reported during the 1980s.

The CLEO stellarator, an $L = 3$ classical stellarator, produced current-less plasma by injecting microwaves at 17.5 GHz without ohmic heating for the first time (Atkinson et al., 1981). Electron energy confinement time was similar to that in ohmically heated plasmas. In W7-A, an $L = 2$ classical stellarator, the plasma current was reduced to zero during NBI heating while keeping the rotational transform unchanged by increasing the current in the helical coils (Bartlett et al., 1981). This current-less operation was successful. MHD instabilities (Lao et al., 2021) such as “tearing modes” were suppressed and energy confinement was improved compared with ohmically heated plasma.

Initiation and heating by ECRH were demonstrated in Heliotron E (Iiyoshi et al., 1982) soon after CLEO, and subsequently this scheme has been established as a standard mode of operation of stellarators. It has also been proved that the advantage of scale in LHD has enabled plasma initiation even by collisions between neutral gas and NBI-particles (Kaneko et al., 1999). This method is useful, since the operational magnetic field is not constrained by the resonance condition required for ECRH.

With regard to plasma current, it should be noted that intrinsic “bootstrap currents” (Sarazin, 2021) driven by the plasma pressure gradient are generated in stellarator plasmas. There are three principal means to control or suppress bootstrap currents among the three leading stellarator concepts noted above. Since quasi-isodynamic stellarators, such as W7-X and Heliotron J, are characterized by weak magnetic shear, bootstrap currents change the rotational transform profile and often generate magnetic islands. In particular, deformation of the plasma boundary defined by chains of magnetic islands must be avoided in order to ensure the divertor function (Geiger et al., 2010). Therefore, minimization of bootstrap currents is incorporated in the optimization of magnetic geometry. In contrast, the heliotron configuration, such as LHD, is characterized by strong magnetic shear, and the magnetic configuration, which incorporates the divertor magnetic structure, is robust against bootstrap currents. The third concept is the “quasi-axisymmetric” stellarator with low aspect ratio. Since its rotational transform in vacuum is small, a contribution from bootstrap currents is intrinsically necessary to optimize this magnetic configuration. Therefore, the QA stellarator can be referred to as a tokamak-stellarator hybrid.

Performance of energy confinement time and its empirical scaling

Needless to say, energy confinement time is a primary parameter for demonstrating the performance of plasma magnetic confinement. Comparative studies of multiple experiments, extending beyond the plasma parameter scans possible in a single device have been developed, as is the case for tokamaks. A pioneering work compiling published data from Heliotron E, W7-A, L2 and Heliotron DR was reported in 1990 (Sudo et al., 1990), and this showed favorable density dependence, which is not seen in tokamaks, and a power degradation (i.e. a reduction in energy confinement time with increasing heating power), as seen in tokamaks. A more comprehensive analysis was conducted by an international collaboration on the International Stellarator Database. This confinement database was compiled by collecting data from medium sized stellarators: ATF, CHS, Heliotron E, W7-A and W7-AS. Careful statistical regression analysis showed an offset between the heliotron/torsatron line, i.e. with a strong positive magnetic shear and a limited magnetic well, and the Wendelstein concept, having very low shear but a magnetic well. The dependence on other operational parameters was, however, very similar for the two concepts. Averaging data across the offset, the International Stellarator Scaling 95 (ISS95) (Stroth et al., 1996) was derived as,

$$\tau_E^{ISS95} = 0.079 a^{2.21} R^{0.65} P^{-0.59} \bar{n}_e^{0.51} B^{0.83} \iota_{2/3}^{0.4},$$

where a , R , P , $\bar{n}_e$, B , and $\iota_{2/3}$ are minor radius in m, major radius in m, absorbed heating power in MW, line averaged density in 10^{19} m^{-3} , magnetic field in T and rotational transform at the two thirds minor radius. The ISS95 scaling was subsequently upgraded to the ISS04 scaling based on an extended database of more than 3000 data points which included data of the large-scale plasmas in LHD and the different magnetic configurations of TJ-II and Heliotron J (see Fig. 8) (Yamada et al., 2005). While a very similar dependence on the key operational parameters has been reconfirmed in the later scaling, a renormalization factor has been introduced for each subgroup to quantify offsets between different magnetic configurations, allowing the energy confinement time to be expressed in a unified scaling law:

$$\tau_E^{ISS04} = 0.134 a^{2.28} R^{0.64} P^{-0.61} \bar{n}_e^{0.54} B^{0.84} \iota_{2/3}^{0.41}.$$

Both ISS95 and ISS04 satisfy dimensional constraints derived from underlying physics consideration and exhibit a gyro-Bohm nature (Jenko, 2021), with $\tau_E^{ISS04} \Omega_i \propto \rho_*^{-2.79}$, where ρ_* and Ω_i are the ion gyro radius normalized by plasma minor radius and the ion cyclotron frequency, respectively. It should be emphasized that these scaling expressions also describe tokamak data surprisingly well by translating rotational transform in stellarators to equivalent plasma current (Dinklage et al., 2007). The study of ISS04 has also suggested that effective “helical ripple” has significant correlation with the renormalization factors noted above and that transport is determined by turbulent transport rather than neoclassical (i.e. collisional) transport (Yamada et al., 2005).

With regard to the isotopic mass effect on the energy confinement time, detailed comparison of hydrogen and deuterium plasmas in LHD has shown no significant dependence on the atomic mass of ions, M (Yamada et al., 2019):

$$\tau_E^{scl} = 0.072 M^{0.00} B^{0.84} \bar{n}_e^{0.76} P_{abs}^{-0.87},$$

which has verified provisional observations in the mid-size stellarators (ATF, W7-AS and Heliotron E) (Stroth et al., 1995; Yamada et al., 2004). The isotope effect, i.e. the observed dependence of the energy confinement time on the fuel isotopic mass, is a long-standing unresolved mystery in tokamaks and this study would contribute to a comprehensive physical understanding. Here it should be noted that a clear mass dependence appears together with the persistence of the gyro-Bohm nature when the scaling expression is rephrased in non-dimensional parameters:

$$\tau_{E,th}^{scl} \Omega_i \propto M^{0.99} \rho_*^{-2.98} \nu_*^{0.19} \beta^{-0.30},$$

where ν_* and β are the electron-ion collision frequency (Sarazin, 2021) normalized by the bounce frequency of the banana orbit (of trapped particles) and the plasma kinetic pressure normalized by the pressure of the magnetic field, respectively.

Fig. 8 Comparison of experimentally measured values of the energy confinement time in stellarator experiments with predictions derived from the ISS04 scaling, which is discussed in the text. A range of tokamak experimental data of H-mode plasmas (Kardaun, 1999) in which the plasma current has been translated into a rotational transform, is also shown for comparison.

H-mode

The H-mode regime of plasma confinement, highlighted by significantly improved confinement, has been studied very intensively in tokamaks since its first discovery on the ASDEX tokamak (Wagner et al., 1982). Since that time, it has been confirmed that the H-mode develops in a variety of stellarators over wide parameter ranges (Wagner et al., 2006). The H-mode transition has been reported from W7-AS (Erckmann et al., 1993), CHS (Toi et al., 1993), LHD (Toi et al., 2005), Heliotron J (Sano et al., 2005), H-1 (Shats and Rudakov, 1997) and TJ-II (Alejandre, 2004). The Tohoku heliac has also induced H-mode by inserting an electric biasing probe (Kitajima et al., 2004). This means that the development of the H-mode is a ubiquitous and fundamental phenomenon among toroidal plasmas. The transition to, and development of, the H-mode is closely linked with the radial electric field and its shear in the edge (Jenko, 2021). The pressure gradient plays a leading role in determining the radial electric field structure in tokamaks, although additional physics mechanisms, while still controversial, remain under investigation (Tynan et al., 2016). In addition to these mechanisms, an intrinsic radial electric field exists due to the ambipolar condition in stellarators (see discussion in the section *Identification of transport properties*).

The first identification of H-mode in a stellarator was performed in plasmas with low magnetic shear on W7-AS (Erckmann et al., 1993). The H-mode transition, accompanied by a characteristic drop of the H_α light emission and an increase of density, was observed in plasmas using an island divertor configuration and operating above a certain threshold density ($4\text{--}5 \times 10^{19} \text{ m}^{-3}$) which were heated by electron cyclotron waves. A steep pressure gradient developed in the plasma edge which correlated with formation of a deep negative electric field inside the magnetic separatrix. Characteristic edge localized MHD modes (ELMs), which expel energy, have been observed, although quiescent H-modes without ELMs have also been found in a narrow operational space above a power dependent critical density. In contrast to the situation in tokamaks, a critical level of heating power, or “power threshold”, was not observed. This may imply a contribution to the H-mode transition of a pre-existing radial electric field due to neoclassical ambipolarity in stellarator plasmas. At higher density, the H-mode in W7-AS developed into another characteristic regime referred to as a high-density H-mode (HDH) (McCormick et al., 2002). The HDH mode exhibits an improvement of energy confinement time by a factor of 2 beyond the prediction of the ISS95 scaling and simultaneously exhibits a significant drop of impurity confinement time. The significant consequence of this behavior is that plasmas in the HDH mode purify themselves (i.e. reduce the impurity concentration) and allow steady-state operation close to the density limit. Observations in Heliotron J share significant commonality with those in W7-AS. The H-mode transition occurs in an isolated narrow range of rotational transforms in the vicinity of rational values in both Heliotron J and W7-AS, which is interpreted as implying that plasma poloidal viscosity plays an important role in the H-mode transition (Wobig and Kisslinger, 2000). The dependence of the transition on the fuel isotope mass, in particular the increased ease of transition in deuterium plasmas compared to hydrogen plasmas, which is clear in tokamaks, was not been identified in Heliotron J and W7-AS.

In the heliotron line, with high magnetic shear, the H-mode transition was driven by increased rotational transform produced by supplemental plasma current in CHS (Toi et al., 1993). While the observed density threshold scaled as in tokamaks, the power threshold was higher by a factor of 2, which was interpreted as being due to the limiter configuration used in these experiments, as opposed to the divertor configuration commonly used for H-mode experiments in tokamaks. H-mode transitions have also been observed in LHD and are most pronounced in high β plasmas at low magnetic field (0.5–0.75 T) (Toi et al., 2005). The improvement of confinement in CHS and LHD resulting from the H-mode transition is limited to several 10s %, compared to a factor of 2 typically observed in tokamaks. Since the edge region is associated with a “magnetic hill” in the heliotron, an “interchange mode” appears immediately on development of a significant pressure gradient, limiting the improvement in confinement.

High beta

Achievement of high beta (β), where β is the kinetic pressure normalized by the pressure of the magnetic field, is a critical mission towards demonstrating an attractive fusion reactor, not only in tokamaks but also in stellarators. While high β is normally favorable, or even essential, for an efficient and economical reactor, it has another important impact on stellarators. Since the confining magnetic field is produced by external coils, these coils should be located as close as possible to the plasma in a stellarator in order to ensure a satisfactory magnetic field configuration. However, the space for the blanket, with about 1 m of thickness, must be accommodated. Then, if slim magnets are to be incorporated, implying low magnetic field and high β value, the reactor size could be reduced.

Since stellarator plasmas are current-less, MHD instabilities which prevent high β operation are driven by the pressure gradient and not by the current density gradient. Therefore, stellarators are free from “kink modes” and “tearing modes,” and the primary concerns are “interchange modes” and “ballooning modes.” Basically, the concept of quasi-symmetry in stellarators involves a shear-less magnetic field profile and MHD stability is secured by a magnetic well. In contrast, the heliotron configuration, which has a radially limited magnetic well, stabilizes MHD instabilities by strong magnetic shear.

Experimental achievement of high β has progressed together with stellarator concept development and advances in heating technology. The first notable result was the achievement of β of 2% in NBI heated plasmas in Heliotron E (Motojima et al., 1985). Subsequently, CHS recorded a slightly higher β of 2.1% (Okamura et al., 1995) and W7-AS extended the range further to β of 3.4% (Weller et al., 2003). The present record is a β value of 5% in LHD (Sakakibara et al., 2008). This reactor-relevant high β in LHD has been sustained for longer than 100 energy confinement times, as shown in Fig. 9. It has been shown throughout these experimental observations that the MHD instability limit to pressure in stellarators is benign (Yamada et al., 2010). MHD-driven

Fig. 9 Achievement and sustainment of high- β plasmas in LHD compared with β values achieved in a representative range of tokamak experiments. The abscissa is the duration of sustainment normalized by the energy confinement time.

disruptions, which terminate the plasma in tokamaks, have not been observed. In general, MHD instabilities are not harmful in stellarators and only degrade confinement. As a result, the β limit is soft and determined by energy confinement and heating power. Although linear MHD theory has been successful in predicting the β limit in tokamaks, stellarator observations have stimulated the development of more sophisticated models to explain the stabilizing mechanism allowing sustained operation at high β . Recent non-linear simulations including kinetic effects of trapped particles (Sato and Todo, 2019) and parallel thermal conductivity (Miura and Nakajima, 2010) are beginning to resolve this issue.

High density

High density operation is favorable for achieving high fusion power, as seen in the density dependence in the scaling of energy confinement time. In particular, high collisionality due to high density mitigates heat losses via neoclassical transport enhanced by a helical ripple in stellarators. High density is also advantageous in mitigating the divertor heat load. The so-called Greenwald density is a well-established criterion for assessment of the density limit in tokamaks (Greenwald et al., 2002), where disruptions often determine the highest achievable density. In contrast to tokamaks, a radiative collapse limits the achievable density in stellarators. Moreover, while steady-state operation of tokamaks benefits from operation at low density and high temperature, in order to ensure high current drive efficiency (Dumont, 2020), stellarators do not have this kind of constraint on operational density.

The most well-established expression of the density limit in stellarators is given by the Sudo scaling (Sudo et al., 1990)

$$n_e^{\text{Sudo}} = 0.25 P^{0.5} B^{0.5} a^{-1} R^{-0.5}$$

where n_e^{Sudo} is in units of 10^{20} m^{-3} . This scaling is based upon observations in medium-sized experiments, such as Heliotron E, W7-A, L2 and Heliotron DR. The background to this expression has been explained by a theory formulating the power balance between heating power and impurity radiation loss (Itoh et al., 2001; Zanca et al., 2019).

Later experiments in W7-AS (Giannone et al., 2000) and LHD (Peterson et al., 2001) showed that the accessible density is consistent with the picture of the Sudo scaling, but observed a significant improvement beyond its prediction. Since the radiative collapse is triggered by edge radiation, the edge density and local concentration of light impurities are considered to be essential parameters (Miyazawa et al., 2008).

Particularly noteworthy features of high density operation in stellarators include the high density H-mode (HDH) in W7-AS, noted previously, and the super-dense-core (SDC) in LHD (Ohyabu et al., 2006). The HDH in W7-AS has provided access to stationary high density operation at densities of up to $4 \times 10^{20} \text{ m}^{-3}$ at 2.5 T (McCormick et al., 2002). The SDC in LHD was discovered when using intensive core fueling by cryogenic pellet injection into plasmas with efficient pumping via a “local island divertor” (LID) (Morisaki et al., 2005). A steep density gradient develops in the core region and forms an extremely high density core. This operation was extended to the helical divertor configuration. When the magnetic configuration forms a thick layer with ergodic field lines in the plasma boundary, the SDC can be formed without active pumping. Under these conditions, the central density has reached $1.2 \times 10^{21} \text{ m}^{-3}$ at 2.5 T (Yamada et al., 2007). The SDC is accompanied by an improvement in energy confinement and the central pressure reaches 1 atm. It should be noted that in neither the HDH in W7-AS nor the SDC in LHD was significant impurity accumulation observed, which is an important result in relation to the potential application of these regimes in a stellarator reactor. Finally, when the rotational transform is replaced by plasma current, which is the key parameter of the Greenwald density in tokamaks, the operational high density regime of LHD and W7-AS far exceeds the Greenwald density (see Fig. 10).

Steady-state operation

Since stellarators can form the confining magnetic field using only external coils, steady-state operation, a key aspect of reactor operation, is intrinsically possible. On the other hand, demonstration of steady-state operation requires a sufficient engineering capability of the device. The key elements are steady-state operation of heating systems and a compatible heat removal capability, in

Fig. 10 Comparisons of the achieved plasma density in stellarator and tokamak experiments with the Greenwald density, $n_{GW} = I_p / \pi a^2$, with n_{GW} the predicted Greenwald density in 10^{20} m^{-3} , I_p the plasma current in MA and a the plasma minor radius in m. Data of the SDC in LHD and the HDH in W7-AS are plotted by translating the rotational transform to an equivalent plasma current. Data from the tokamak experiments Alcator-C, DIII and PBX (Greenwald et al., 2002), and the reversed field pinch experiment RFX-mod (Puiatti et al., 2009) are shown for comparison.

particular, from divertor plates. For example, although the ATF device employed normal Cu conductor for the helical coils, it was possible to operate in steady-state at a magnetic field at 0.5 T. ECRH operating at 28 GHz with a power level of 70 kW produced a current-less plasma with a pulse length greater than 1 h (4667 s) (Jernigan et al., 1995). Plasma parameters were modest (a density of several $\times 10^{18} \text{ m}^{-3}$ and a temperature of around 100 eV). The steady-state operation regime has been greatly extended in LHD by exploiting the superconducting coils. The typical steady-state discharge sustained by 0.26 MW of ECRH and 0.94 MW of ion cyclotron radiofrequency heating (ICRF), i.e. 1.2 MW total heating power, at 2.75 T for 2859 s exhibited plasma parameters with a density of $1.2 \times 10^{19} \text{ m}^{-3}$ and a temperature of 2 keV. The total injected heating energy to the plasma reached 3.4 GJ (Kasahara et al., 2014). While plasma parameters, as well as the temperature of the divertor plates, were held constant, a temporal change of recycling fuel gas from the plasma facing surfaces was observed in conjunction with the evolution of co-deposition of divertor material (carbon) and fuel gas on the wall (Motojima et al., 2015). The plasma pulse was terminated as a result of flaking of material from the wall or divertor, leading to penetration of impurities into the plasma (Shoji et al., 2016).

Figure 14 in Wolf et al. (2019) summarizes the performance of LHD and W7-X in terms of the achieved fusion triple product as a function of plasma pulse length and compares the results of several leading tokamak experiments. The W7-X stellarator foresees the production of stationary plasmas lasting for 30 min. With 10 MW of heating and an actively cooled divertor (Hathiramani et al., 2018).

Control of detached plasma

Limiting the divertor heat load in a fusion reactor to the level which can be handled by practical engineering solutions (Federici et al., 2021) is one of most critical issues and, while experimental progress has been made in this respect, there remains a significant discrepancy between the requirements in a fusion reactor and experimental achievements. Moreover, considerable further work is required to develop a fully reliable predictive theory. In this regard, stable detachment of the plasma in front of the divertor plate is a prerequisite to mitigate divertor heat load, regardless of whether a stellarator or tokamak forms the reactor core.

The HDH regime in W7-AS has been investigated intensively with regard to its compatibility with detachment. While energy confinement improved almost linearly until the plasma density reached the threshold of partial detachment, it decreased as the density increased further due to the encroachment of radiation into the core region following the onset of partial detachment. The ratio of radiation to heating power reached values of up to 90% at partial detachment. Considerable neutral compression in the divertor region was observed simultaneously, which is a precondition for efficient active pumping of exhaust gases, including helium. Further increase of density towards full detachment caused the penetration of the radiation layer into the core and eventually led to a radiative collapse. While favorable detachment behavior was observed in the HDH regime, stable detachment was obtained in a specific geometry surrounded by a sufficiently large magnetic island to reduce the penetration of neutral gases and impurities into the core plasma, i.e. to improve neutral and impurity screening efficiency (Feng et al., 2005).

Detachment often suffers from a thermal instability which causes radiative collapse of the plasma. In LHD, it has been found that application of resonant magnetic perturbations (RMP) promotes local enhancement of radiation and consequently facilitates the access to stable detachment. The RMP with $m/n = 1/1$ poloidal and toroidal mode numbers generates a magnetic island in an edge ergodic layer (Kobayashi et al., 2019). Although the energy confinement decreases due to reduction of the effective plasma radius by the generated magnetic island, the pressure profile becomes peaked during detachment. This suggests that the core confinement is

not degraded even with enhanced radiation and reduced divertor flux. Impurity penetration is prevented by screening through friction with the downstream particle flux. The observations in LHD have a great deal in common with the HDH regime.

Stable detachment with radiation reaching the level of the absorbed heating power in the core plasma has been achieved in W7-X (Zhang et al., 2019). Experiments in W7-X exhibit stable sustainment of a detached plasma for 28 s at $1.1 \times 10^{20} \text{ m}^{-3}$ with 5 MW of ECRH. The radiation fraction is at a level of 80–90% and the duration is limited by the capacity of the uncooled divertor used in these experiments. Following the upgrade to an actively cooled divertor and to an increased heating power of 10 MW, these favorable results will be investigated further in the extended parameter regime.

Identification of transport properties

In relation to plasma transport and confinement in the stellarator configuration, the major concern arises from the influence of neoclassical transport enhanced by the intrinsic “helical ripple” of the magnetic field. According to neoclassical theory, the confinement capability of the stellarator is significantly degraded by the enhancement of neoclassical transport as the collisionality decreases, i.e., as the temperature increases. The neoclassical theory of plasma transport in stellarator plasmas is well established and based on a rigorous formulation. On the other hand, competitive transport processes produced by turbulence often mask the neoclassical aspects of plasma transport.

Optimization of the magnetic field to reduce neoclassical transport has been driven by theory (Shaing and Hokin, 1983; Lotz and Nührenberg, 1988; Mynick, 2006). Each approach has been validated in experiments and has been successful to a significant extent. Nowadays, it is well accepted that, when neoclassical transport is reduced, heat transport in stellarators is governed by short-wave turbulence, as in tokamaks. For example, in LHD, the inward shift of the magnetic axis, i.e. to smaller major radius, has a favorable influence derived from the common physics of quasi-isodynamics. While, in the case with the inward shifted magnetic axis, the heat transport and the energy confinement time are not degraded even in the reactor-relevant low collisionality regime, cases with the outward shifted magnetic axis exhibit confinement degradation with decreasing collisionality, which implies enhancement of the neoclassical transport (Yamada et al., 2001a). Another important observation in this comparison is that improvement of confinement by the inward shift persists in the high collisionality regime, where helical ripple transport is suppressed. Since turbulent transport plays an essential role in the high collisionality regime, it is concluded that the inward shift of the magnetic axis suppresses turbulent transport. Indeed, a more comprehensive study of the international stellarator database indicated that the normalization factor relative to the average scaling, which depends on magnetic configuration, has a correlation with the effective helical ripple, and suggested that neoclassical optimization could suppress turbulent transport (Yamada et al., 2005).

A comparative study of dimensionally similar plasmas has been established in ATF (Murakami et al., 1993), W7-AS (Stroth et al., 1993) and LHD (Yamada et al., 2001b) in order to clarify the characteristics of heat transport, in particular, its dependence on normalized gyro radius, ρ^* . All analyses have shown a common gyro-Bohm nature, that is the heat diffusivity, χ , scales with $\rho^* \chi_B$, where $\chi_B = 16T/(eB)$ is the Bohm diffusivity, and T and e are the temperature and elementary charge respectively. Recent experiments in LHD made a detailed comparison of dimensionally identical plasmas with hydrogen and deuterium fuel and showed that $\chi \propto M\rho^* \chi_B$, with M the isotopic mass of the plasma ions (Yamada et al., 2019). The identified mass dependence is consistent with the characteristics of the energy confinement time, but the underlying physics determining this dependence remains an open issue.

It should be noted that, since the magnetic field in a stellarator is not axisymmetric, a radial electric field is generated by the ambipolar condition to balance electron and ion particle fluxes (Hastings et al., 1985), while in an axisymmetric system, such as a tokamak, particle fluxes are intrinsically ambipolar. The radial electric field generated in the low collisionality regime in stellarators has significant potential to suppress neoclassical transport. Many experiments have shown that a radial electric field is generated by the balance of neoclassical fluxes, even in cases where turbulence dominates heat and particle transport (Yokoyama et al., 2007). This implies that turbulent transport is ambipolar. It should be noted that there exist multiple roots in the neoclassical ambipolar condition. In particular, the “electron root,” which is developed when the flux of electrons trapped in the helical ripple dominates over the ion flux, produces a strong positive radial electric field. The resultant, greatly reduced, neoclassical transport allows very high electron temperatures to be achieved. This mode is referred to as Core Electron Root Confinement (CERC). In addition, radial variation between the electron and the ion root results in a strong electric field shear, which produces sheared poloidal flows of plasma, and this may lead to suppression of turbulence (Jenko, 2021).

Particle transport has not been analyzed in as much detail as heat transport and is less understood. Nonetheless, a pronounced feature that has commonly been observed in stellarator plasmas is a hollow radial density profile. Unlike sources of heat, the particle source is usually localized in the edge and then a simple diffusive analysis predicts a flat density profile. While the so-called anomalous inward pinch, which has been proposed to explain the peaked density profile observed in tokamak plasmas, is not usually observed in stellarator plasmas (Takenaga et al., 2008), the density profile tends to be hollow due to an outward convection driven by the temperature gradient, which is documented in the framework of neoclassical transport (Yamaguchi et al., 2007). This trend is expected to become more pronounced in large stellarators with low collisionality (Maassberg et al., 1999).

Other important physical processes driven by neoclassical transport are the bootstrap current and parallel viscosity. Both are due to transport parallel to the magnetic field, in contrast to heat and particle transport. With regard to the bootstrap current, good quantitative agreement with the predictions of neoclassical theory has been confirmed in ATF (Murakami et al., 1991b), CHS (Yamada et al., 1994) and Heliotron J (Motojima et al., 2007). In addition, reversal of the bootstrap current by changing the plasma elongation was observed in ATF and CHS, in agreement with theoretical predictions relating to the situation where the major contribution to the bootstrap current is switched from trapped particles in the depressed magnetic field on the outboard side to those in the

helical ripple. Damping of toroidal plasma flow owing to parallel viscosity was investigated by changing the magnetic field modulation in CHS (Ida et al., 1991). It was found that the toroidal velocity profile was dominated by the perpendicular viscosity, i.e., perpendicular momentum transport, when the modulation was weak. As the magnetic toroidal modulation increased, the toroidal velocity became dominated by the parallel viscosity. This observed tendency is consistent with neoclassical theory and has shown quantitative agreement with theory to within a factor of 3.

In summary, heat and particle transport in stellarator plasmas is dominated by turbulence and the radial electric field determined by the neoclassical ambipolar condition has a noteworthy impact on the turbulence. Moreover, neoclassical effects are pronounced in parallel transport processes associated with trapped particles, as manifested in phenomena such as the bootstrap current and parallel viscosity. A diagram to summarize the linkages among transport processes will be given in the next section, including a consideration of 3-D effects.

3D physics

Stellarators are intrinsically 3D magnetic configurations. Nowadays, tokamaks also require a 3D physics analysis to deal, for example, with physics processes related to the use of resonant magnetic perturbation to suppress/mitigate ELMs, with the damping of flows due to neoclassical toroidal viscosity and with plasma flows impeding magnetic island formation. Transport in the divertor and scrape-off layer is inevitably 3D, even in a tokamak. There is commonality in these physics issues between stellarators and tokamaks. Related examples have already been discussed in previous sections.

The theoretical description of a 3D MHD equilibrium has been confirmed in experiments on CHS (Yamada et al., 1992) and W7-AS (Weller et al., 2003). Beginning with the “Shafranov shift” due to plasma pressure, the deformation of flux surfaces, including the generation of magnetic islands and ergodic layers, is well described by 3D MHD equilibrium numerical codes such as VMEC (Hirshman, 1986) and HINT (Suzuki et al., 2006, 2013). In addition, spontaneous stochasticization of the magnetic field has been confirmed by heat pulse propagation and flow damping in a detailed experiment in LHD (Ida et al., 2017).

As describe in the previous section, the radial electric field generated through neoclassical transport in 3D affects turbulence. Moreover, the geometrical effect of the effective helical ripple and the isotope effect have been identified in experiments, and advanced gyro-kinetic simulations are beginning to clarify the responsible physics mechanism through the characteristics of “zonal flows” (Jenko, 2021) in 3D (Watanabe et al., 2008; Nakata et al., 2017). Here it should be emphasized that the first experimental identification of a zonal flow was carried out in CHS (Fujisawa et al., 2004). The linkage of various physical mechanisms involved in the determination of transport in toroidal plasmas is summarized in Fig. 11 (Yamada, 2009). Radial profiles of temperature and density are determined by turbulence self-consistently with gradients of temperature and density, shear of the radial electric field and zonal flows in 2D. In contrast, or complementarily, the radial electric field due to 3D neoclassical transport affects the shear of the radial electric field, the zonal flows via collisional damping and neoclassical transport itself.

Status of current leading projects

The device parameters of LHD and W7-X, the two largest stellarator experiments, are summarized in Table 2.

Large helical device (LHD)

The Large Helical Device (LHD), shown in Fig. 2a–c and located in the National Institute for Fusion Science (NIFS, situated in Toki-city, Japan), is based on a heliotron concept which employs a pair of continuous helical coils (Iiyoshi et al., 1990; Special Issue, 2010). The NIFS is an inter-university research institute and the LHD is open to research collaborators. The detailed device

Fig. 11 Schematic inter-linkage of plasma transport processes in 3-D. ‘NC’ refers to neoclassical transport theory. The various contributing physics processes shown in the diagram are discussed in the text.

Table 2 Specifications and typical plasma parameters of LHD and W7-X.

	<i>LHD</i>	<i>W7-X</i>
Major radius (m)	3.7	5.5
Minor radius (m)	0.63	0.55
Plasma volume (m ³)	29	30
Magnetic field (T)	2.85	2.5
Rotational transform		
Center	0.35	0.8
Edge	1.5	1.2
Heating power		
NBI (MW)	34	2
ECH (MW)	5	7
ICH (MW)	3	—
Achieved parameters		
Central electron temperature (keV)	20	8
Central ion temperature (keV)	10	3.5
Central electron density (10 ²⁰ m ⁻³)	12	1.4
Fusion triple product (s · keV · 10 ¹⁹ m ⁻³)	5.2	6.8
Beta (%)	5.1 (0.425 T)	0.55 (2.5 T)
Pulse length	48 min (1.2 MW)	30 s (5 MW)

specification and achieved plasma performance of LHD are compared with those of W7-X in [Table 2](#). LHD has three up-down pairs of poloidal coils in addition to a pair of helical coils. All these coils are superconducting (NbTi) with the capability for fully steady-state operation ([Motojima, 1994](#)). Adjustment of the currents of the poloidal coils enables changes in the radial position and shape of the plasma cross-section. Optimization of the magnetic configuration has been carried out with the constraints set by the continuous helical windings, which accommodate a unique pronounced feature in the form of a built-in divertor configuration ([Ohyabu et al., 1994](#)). Outside the closed flux surfaces, field lines are guided by a pair of helical coils through the ergodic layer to the built-in double null divertor. The vacuum vessel wall is stainless steel, as shown in [Fig. 6](#). LHD also accommodates 10 pairs of perturbation coils (with normal conductors) to compensate error fields and to generate resonant magnetic islands intentionally ([Ohyabu et al., 1995](#)).

Since its initial operation in 1998 ([Iiyoshi et al., 1999](#); [Motojima et al., 2000](#)), LHD has operated without serious problems. The number of cool-down and warm-up cycles, and the number of excitations of the superconducting coils had reached 21 and 1890 respectively by 2020. A variety of sophisticated diagnostics have been installed in conjunction with enhancement of the heating capability. The plasma volume is about 30 m³, which is much greater than preceding stellarators, and LHD was the first stellarator comparable in scale to large tokamaks. About 40 MW of total heating power is delivered by electron and ion cyclotron resonance heating and by two types of neutral beam injection, tangential beams with negative ion sources (180 keV injection energy) and perpendicular beams with positive ion sources (80 keV injection energy) ([Takeiri et al., 2006](#)). Divertor operation has been also developed. The open divertor configuration in the inboard region, where the particle flux is concentrated, has been rearranged into a closed divertor configuration ([Morisaki, 2013](#)) with cryogenic pumps and getter pumps. The replacement of the carbon divertor target plates with tungsten target plates is planned and a provisional partial test has started. Deuterium experiments started in 2017, which facilitated a significant increase in the power of neutral beam injection ([Osakabe et al., 2018](#)) and provided the opportunity to study the influence of ion isotope effects on plasma physics processes ([Yamada et al., 2019](#); [Ida et al., 2020](#)). In particular, a landmark discovery revealed that the so-called inward shifted magnetic configuration suppressed both neoclassical and turbulent transport while maintaining MHD stability ([Yamada et al., 2001a](#)). This finding is shared by physics under optimization by quasi-isodynamics. Further important experimental results in LHD included the production of a reactor-relevant value of central ion temperature of 10 keV ([Takahashi et al., 2018](#)), the achievement of central electron density of $1.2 \times 10^{21} \text{ m}^{-3}$ ([Yamada et al., 2007](#)), production of high plasma pressure, with a β value of 5% ([Sakakibara et al., 2008](#)), and establishment of 50 min operation of a plasma with a temperature of 2 keV using 1.2 MW of heating power (3.4 GJ of injected energy) ([Kasahara et al., 2014](#)).

Wendelstein 7-X (W7-X)

Wendelstein 7-X (W7-X), shown in [Fig. 2d–f](#) and located in the Max-Planck-Institut für Plasmaphysik (MPP, situated in Greifswald, Germany), is an optimized advanced stellarator ([Nührenberg, 1995](#)) based upon a successful proof-of-principle demonstration in the preceding device W7-AS ([Grieger et al., 1985](#)). Deviation of confined charge particles from the magnetic flux surfaces are minimized, as are the “Pfirsch-Schlüter” ([Galvão and Canal, 2021](#)) and bootstrap currents which deform magnetic flux surfaces. The concept of an advanced “quasi-isodynamics” stellarator has been driven by theory ([Nührenberg and Zille, 1998](#)). This is a unique

approach in which an optimized magnetic configuration is given first and then external coils are designed to realize the required magnetic configuration. Therefore, a combination of non-planar modular coils is a prerequisite to satisfy the design constraint.

W7-X is also a superconducting (NbTi) device with a steady-state capability (Sborchia et al., 2006). The magnetic configuration of W7-X is folded into five periods around the torus and each period has five pairs of different-type modular coils. Together with 20 planar coils which control the rotational transform, W7-X has 70 superconducting modular coils in total (Wanner et al., 2001). The magnetic field is fine-tuned by two kinds of control coils (with normal conductors) located outside (Rummel et al., 2014) and inside of the vacuum vessel (Füllenbach et al., 2020). These correction coils are used to correct error fields and tailor the magnetic field at the plasma boundary. The plasma volume is 30 m^3 , which is the same as in LHD. The modular coil system forms closed flux surfaces bounded by island divertors. A pair of top and bottom divertors, where heat and particle fluxes are concentrated, are arranged within each period. Construction was launched in 2002 and plasma experiments started in 2015 after overcoming significant manufacturing difficulties in the complex modular coils (Risse et al., 2016). The first operation phase (OP1.1) was dedicated to basic commissioning of the facility with the limiter configuration under limited heating power and pulse length (Klinger et al., 2017). A divertor without active cooling was then installed and the subsequent operation phase (OP1.2) was executed in 2017–18 (Bosch et al., 2020). Although the heating power and total injected energy were limited (6 MW and 200 MJ respectively), operational performance was extended considerably and basic features of the quasi-isodynamics optimization were confirmed (Dinklage et al., 2018). The *fusion triple product* reached $6.5 \times 10^{19} \text{ m}^{-3} \text{ keVs}$, which is the record value achieved in stellarators (Klinger et al., 2019). Stable high density operation above the cut-off density of the 2nd harmonic electron cyclotron resonance heating in X-mode has been demonstrated by use of the second harmonic O-mode (Laqua et al., 2019). A further important achievement is the demonstration of stable sustainment of detached plasmas for 30 s, which strengthens the strategy towards high-power steady state operation.

Installation of actively cooled divertor targets (Hathiramani et al., 2018) following OP1.2 will enable 30-min operation with heating power of 10 MW. Operation phase OP2, which will make use of these full device capabilities, is planned in 2021.

Medium sized stellarators

While the poloidal shaping of tokamak plasmas is generally converging to a certain range in plasma elongation and triangularity, stellarator plasmas still exhibit considerable diversity. The extension of the plasma parameters towards the reactor-relevant regime is being advanced by experiments in LHD (heliotron) and W7-X (advanced stellarator), while distinctive concepts are being explored in medium-sized stellarators experiments.

TJ-II (CIEMAT, Spain)

TJ-II is a flexible “*heliac*” which has been in operation at Spain’s National Fusion Laboratory in CIEMAT (Madrid, Spain) since 1997 (Alejandre et al., 1999). The device was designed through a collaboration of CIEMAT, Oak Ridge National Laboratory (ORNL, USA) and Max-Planck-Institut für Plasmaphysik (MPIPP, Germany) (Harris et al., 1985). It has two central coils which are interlinked with 32 toroidal coils (see Fig. 7). One of the central coils is a simple circular coil and the other is a helical coil, which winds helically around the circular central coil. Investigations of plasma behavior focus, in particular, on the characteristics of turbulence (Hidalgo et al., 2004; Estrada et al., 2016) by making full use of the flexibility of the magnetic configuration and the intensive diagnostics for measuring plasma flows and fluctuations (Melnikov et al., 2017).

HSX (Wisconsin University, USA)

HSX stands for Helically Symmetric eXperiment and the device started operation in 1999 (Anderson et al., 2002; Gerhardt et al., 2002). HSX has 48 twisted modular coils which generate the confining magnetic field (see Fig. 7), applying the concept of “*quasi-helical symmetry*” (Anderson et al., 1995). Toroidal effects are minimized and the magnetic field configuration is described by a uniform toroidal field and a modulated helical field with a single helicity. Therefore, HSX possesses common features with axisymmetric tokamaks in the direction of symmetry, and the comparisons made of plasma physics properties with those observed in tokamaks attract considerable physics interest. The magnetic configuration is characterized by a large aspect ratio of 10 and a toroidal field period of 4. The major goal of HSX is the demonstration of the advantage of helical symmetry, in particular, in relation to neoclassical transport and to turbulence driven by magnetic field curvature.

Heliotron J (Kyoto University, Japan)

Heliotron J at Kyoto University (Uji, Japan) belongs to an extended family of devices exhibiting “*quasi-poloidally symmetry*.” A magnetic configuration satisfying isodynamics with a magnetic well is formed by tailoring the helicity and bumpiness of the magnetic field. Unlike HSX and W7-X, which share common features of quasi-symmetry, Heliotron J employs a combination of a continuous $L = 1$ helical coil and toroidal field coils (see Fig. 7), rather than modular coils (Wakutani et al., 2000). The toroidal field period is 4 and there are four straight sections and four curved sections. Experiments started in 1999 (Obiki et al., 2001). The project aims at the demonstration of the improvement of confinement capability by isodynamics. Confinement improvement due to achievement of the H-mode (Sano et al., 2005) and generation of an internal transport barrier (Kenmochi et al., 2020) has been confirmed in the experiment.

Introduction

The physics of the Reversed Field Pinch, previously introduced in [Galvao and Canal \(2021\)](#), has achieved in the last years a significant progress from both the experimental and the theoretical point of view. Experiments have been performed in various devices of different sizes. Among these, the largest is RFX-mod in Padova (Italy), which obtained impressive improvements of the performance in high current operation with the spontaneous occurrence of helical equilibria characterized by magnetic order. In MST in Madison (USA), the active control of plasma current profile showed to be effective in inducing tokamak-like confinement properties.

The experiments have been accompanied and inspired by intense fully 3D nonlinear visco-resistive MHD simulations, mainly focused on the investigation of the dynamics of the RFP's magnetic self-organization processes. Current profile control, successfully tested experimentally, was inspired by MHD modeling. The bifurcation toward the single-helicity regime, at first discovered in high viscosity simulations, emerged in experiments. Subsequently, the experimental MHD dynamics were reproduced with extremely good agreement when a helical boundary was included in the simulations.

A positive trend of confinement with plasma current characterizes RFP performances, as presented in [Fig. 1](#), where the central electron temperature is plotted as a function of the plasma current for the RFX-mod database.

A significant upgrade of the RFX-mod device is presently underway with the aim of confirming such scaling.

The RFP can operate at large current density (no physical current limit exists), which implies that high particle density regimes can be explored (the RFP obeys an empirical density law similar to that of tokamaks). The RFP plasmas, being dominated by self-organization processes, are almost disruption free and the ideal beta limit is very large (around 40%).

Interesting properties of the energetic ion confinement have been highlighted in RFP in the last years. Fast ion confinement is almost classical and largely better than the thermal particle confinement, even in the presence of a stochastic magnetic field. Values of energetic ion beta in the core above that expected for alpha particle in a reactor have been achieved.

The magnetic self-organization aspects of the RFP, such as the magnetic dynamo and tearing mode activity, as well as the ion heating and acceleration observed to occur during magnetic reconnection phenomena, are interesting not only from a magnetic confinement point of view but also for their natural connections to astrophysics.

The chapter is organized as follows: in section [The RFP devices](#) the characteristics of the main RFP devices are introduced; section [The RFP equilibrium](#) presents the basic features of the RFP equilibrium; section [The RFP MHD dynamics](#) is dedicated to the dynamics of RFP plasmas, the magnetic reconnection processes, and on the magnetic topology changes induced by tearing modes activity with particular emphasis on the spontaneous bifurcation towards a helical equilibrium; section [Particle transport and confinement](#) introduces the basic physics of particle and impurity transport in the RFP; section [MHD control in the RFP](#) is dedicated to a description of the various approaches for RWM control and of its relevance in determining the confinement properties of the configuration and of the results of real-time tearing mode control; in section [Energetic ion confinement and stability](#) the interesting confinement properties of fast particles are summarized; section [Inductive current drive and profile control](#) is devoted to the performance improvement obtained thanks to inductive control of the current profile; section [Plasma-wall interactions issues](#) describes the main plasma-wall interaction issues; in section [Density and limit](#) the operative limits in terms of plasma density and beta are discussed along with the small-scale stability properties of RFP plasmas; in section [Neoclassical bootstrap current at high \$\beta\$](#) a brief estimation of the expected bootstrap current fraction is given.

Fig. 1 Central electron temperature as a function of plasma current in RFX-mod. Red points refer to deuterium plasmas. Adapted from Piovan R, Bettini P, Bustreo C, et al. (2018) A continuously pulsed reversed field pinch core for an ohmically heated hybrid reactor. *Fusion Engineering and Design* 136: 1489–1493. <https://doi.org/10.1016/j.fusengdes.2018.05.040>

Table 1 Main RFP devices and their characteristics.

	RELAX	EXTRAP-T2R	TPE-RX	MST	KTX phase1(phase2) (projected)	RFX-mod
R/a (m)	0.5/0.25	1.24/0.18	1.72/0.45	1.5/0.5	1.4/0.4	2/0.459
Shell time τ_w (ms)	5	12	300	1100	40	100
Max I_p (MA)	0.12	0.3	0.45	0.6	0.5 (1)	2
Pulse length (ms)	3.5	100	80	100	–	500
Max T_e (keV)	0.3	0.3	1	2.0	0.3 (0.8)	1.5
n_e range 10^{19} m^{-3}	0.2–3	0.5–2	0.5–1	1–4	1–10	1–8

The RFP devices

Several RFP devices, listed in **Table 1**, have been in operation since the 1990s. RFX-mod (formerly RFX, [Gnesotto et al., 1995](#)), at Consorzio RFX in Padova, with $R = 2 \text{ m}$ and $a = 0.459 \text{ m}$, being R and a the major and minor radius respectively, reached the target of a maximum plasma current up to 2 MA. It is equipped with a thin copper shell with $\tau_w = 100 \text{ ms}$ ($\tau_w = \mu_0 a \delta \sigma$, where δ is the wall thickness and σ is the wall conductivity) and a system of actively controlled saddle coils for thin shell operations ([Sonato et al., 2003](#)). An upgrade of the RFX-mod machine (dubbed RFX-mod2) is presently being implemented ([Marrelli et al., 2019b](#); [Peruzzo et al., 2017, 2019](#); [Zuin et al., 2017](#)) with relevant magnetic front-end modifications. Its main aims are the reduction of the amplitude of tearing modes and of the associated magnetic chaos and the mitigation of the plasma wall interaction, locally enhanced by wall-locking.

The MST device, operating at the University of Wisconsin Madison, United States ([Dexter et al., 1991](#)), ($R = 1.5 \text{ m}$, $a = 0.50 \text{ m}$) can reach up to 0.6 MA plasma current. A 5-cm-thick aluminum shell serves as both the vacuum chamber and the equilibrium field magnet. Shell minor radius is 0.52 m with graphite plasma limiters. A 1 MW, 25 keV, 20 ms neutral beam injector is installed and used to study fast ion confinement and stability.

EXTRAP-T2R ([Brunsell et al., 2001](#)), at the Royal Institute of Technology, Stockholm, Sweden, ($R = 1.24 \text{ m}$, $a = 0.18 \text{ m}$, maximum plasma current = 0.3 MA) has a copper shell with shell penetration time of 12 ms. Its experimental activity is mainly focused on the development of advanced feedback tools for the control of MHD instabilities.

The TPE-RX device ([Yagi et al., 1999a,b](#)) RFP ($R = 1.72/a = 0.45 \text{ m}$), with a multiple layer shell made of a close fitting thin one (1 mm copper) ($b/a = 1.08$) and a thick one (5 cm aluminum) was operated until 2007 ([Koguchi et al., 2009](#)).

RELAX is a low aspect ratio RFP ([Masamune et al., 2007](#)) ($R = 0.51 \text{ m}$, $a = 0.25 \text{ m}$, maximum plasma current = 0.12 MA) operated at the Kyoto Institute of Technology, Japan and is mainly devoted to the study of Single Helicity plasmas, MHD stability and the generation of bootstrap current at a low aspect ratio ([Masamune et al., 2009](#)).

The KTX device ([Liu et al., 2014, 2017](#); [Zheng et al., 2012](#)) in operation at the University of Science and Technology in Hefei, China, ($R = 1.4 \text{ m}$, $a = 0.4 \text{ m}$) has a magnetic boundary similar to that of the RFX-mod and is planned to produce a plasma current up to 1 MA, with an active MHD control system. The KTX device aims to investigate the fluctuation induced transport in high temperature RFP plasmas by means of newly developed diagnostics tools ([Liu et al., 2019](#)).

The RFP equilibrium

The RFP equilibrium is a paramagnetic configuration: the plasma current profile arranges in a way to ensure equilibrium and generate most of the toroidal flux. Conversion of poloidal into toroidal flux occurs through a dynamo process proportional to the plasma current. The main parameters to describe a RFP equilibrium are the *pinch parameter* Θ :

$$\Theta = \frac{B_\theta(a)}{\langle B_\phi \rangle}$$

and the *reversal parameter* F :

$$F = \frac{B_\phi(a)}{\langle B_\phi \rangle}$$

negative for a RFP plasma, $\langle B_\phi \rangle$ being the average of the toroidal magnetic field over a poloidal cross section, a the plasma minor radius.

F and Θ are experimentally found to follow some trajectory in the (F, Θ) plane, i.e. are not independent quantities. The following family of functions

$$\mu(r) = \mu_0 \left(1 - \frac{r}{a}\right)^\alpha$$

gives a good cylindrical approximation of the axisymmetric part of the parallel current profile measured in experiments (see e.g. in Fig. 1b of Bodin, 1990).

The plasma current has its maximum at the magnetic axis and decreases to zero at the edge (Antoni et al., 1986; Ji et al., 1995).

The toroidal and poloidal components of the magnetic field are of comparable amplitude in a RFP, as shown in Fig. 2, where the radial profiles of the normalized magnetic fields are compared to those of a tokamak configuration. In contrast to the tokamak, magnetic field lines in a RFP are almost poloidal and the toroidal current is pushed to values above the Kruskal-Shafranov threshold.

The cylindrical safety factor $q(r) = rB_\phi/RB_\theta$ turns out to be a decreasing function of the radius, with $q(0) \approx a/2R$ and $q(a) \leq 0$, as shown in Fig. 3. The toroidal field at the plasma edge is in the opposite direction with respect to the core, hence the name of the configuration. With such a $q(r)$ profile, many resonant surfaces exist for $m = 1$ tearing modes with $n \geq 2R/a$, where m and n are the poloidal and toroidal mode numbers of the usual Fourier decomposition, along with those for $m = 0$ modes at the $q = 0$ surface.

In this equilibrium, helical MHD instabilities (resistive kinks) are triggered and nonlinearly saturate at finite amplitudes with the help of the strong radial decrease of the toroidal field at the edge. These modes, also named dynamo modes, produce helical perturbations of the plasma current, which, in a naïve analogy with a current-carrying wire in a cylindrical flux conserver (Escande et al., 2000a), induces a solenoidal effect, which increases the magnetic field and flux inside the kinked wire. In the presence of a flux conserver a decrease of the magnetic field and flux outside is also imposed, which is at the origin of the magnetic field reversal.

The dynamo process underlying the RFP configuration is thus a mere consequence of magnetic relaxation, as revealed by nonlinear visco-resistive MHD simulations (Bonfiglio et al., 2005). The helical distortions requires a modulation of the current density along current lines and hence the existence a modulated electric field (electrostatic in the case of a stationary saturated perturbation), which drives an $\mathbf{E} \times \mathbf{B}$ motion whose non axis-symmetric part is the dynamo velocity field.

It is worth noting that the helical deformation due to the saturated kink makes RFP plasmas similar to stellarator ones, but also that, while in a stellarator the magnetic field is almost completely defined by externally driven currents, in a RFP the magnetic field is

Fig. 2 Radial profiles of the Toroidal (B_ϕ) and poloidal (B_θ) magnetic fields (normalized to the on-axis toroidal field value) for a Reversed Field Pinch and a Tokamak. Taken from Ortolani S, and Schnack DD (1993) *Magnetohydrodynamics of Plasma Relaxation*. Singapore: World Scientific.

mostly produced by currents flowing inside the plasma. As a consequence, the RFP, corresponding to a full MHD relaxation of the magnetic field, can be considered as resilient to disruptions.

The RFP MHD dynamics

In the setting-up phase of an RFP plasma discharge, an initially flat q -profile evolves, exhibiting a series of local minima at the edge, which provide a source for kink instability (Robinson, 1971). As the plasma current is raised, various resonances enter the plasma region and the associated current-driven $m = 1$ modes with increasing toroidal mode number n occur, producing the poloidal current which amplifies the toroidal flux (Caramana et al., 1983). Subsequently, the toroidal flux in the flat-top phase is observed to be generated either continuously or during discrete events, associated with global rearrangements of the magnetic configuration through magnetic reconnection phenomena. Visco-resistive MHD simulations have offered an insight into the dynamics of such events (Ho and Craddock, 1991; Cappello and Biskamp, 1996a,b; King et al., 2012; Sauppe and Sovinec, 2016).

The magnetic equilibrium and the magnetic boundary determine the frequency and the amplitude of such events (Hattori et al., 1991; Watt, 1983). Large bursts of modes with $m = 1$ and $m = 0$ and low toroidal mode numbers (Verhage et al., 1978; Almagri et al., 1992; Hedin, 1998; Hokin et al., 1991; Lorenzini et al., 2008a,b; Momo et al., 2020) are signs of reconnection processes, associated with global relaxation of the current profile (Brower et al., 2002). This phenomenon is toroidally localized, being induced by nonlinear mode phase alignment (Howell et al., 1987). The generation of localized current sheets parallel to the edge magnetic field has been directly measured in RFX-mod (Zuin et al., 2009) and in MST (Crocker et al., 2003; Piovesan et al., 2008). An example of the dynamics of a reconnection process is shown in Fig. 4.

An important feature of this figure is in panel (e), where the ion heating phenomenon occurring as a consequence of the reconnection process is clearly visible. A large fraction of the magnetic energy released during reconnection events is indeed converted into ion thermal energy, (Scime et al., 1992; Hörling et al., 1996; Gangadhara et al., 2007, 2008). Ion heating in MST plasmas reveals that it is charge and mass dependent (Fiksel et al., 2009; Kumar et al., 2013) and anisotropic in space with $T_{i\perp} > T_{i\parallel}$ (Magee et al., 2011). Moreover, an energetic ion tail forms spontaneously with a power-law distribution. This has the effect of significantly enhancing the neutron rate from fusion reactions in deuterium plasmas in MST (Magee et al., 2011), as also confirmed in RFX-mod plasmas (Zuin et al., 2015).

In the relaxation phase an outward propagating heat pulse is detected, indication of the presence of stochasticity due to the multiple $m = 1$ modes (Frassinetti et al., 2005b).

During discrete reconnection events, rapid and spontaneous changes of the radial profile of the toroidal plasma rotation occur, sign of enhanced radial transport of toroidal momentum, about two orders of magnitude more rapid than what would be expected from classical viscosity. This effect has been interpreted as due to nonlinear interactions of multiple tearing modes producing internal torques that redistribute momentum along the plasma radius (Hansen et al., 2000).

This nonlinear coupling of tearing modes is also responsible for the toroidally localized deformation of the plasma column, named Slinky or Locked Mode in RFP literature (Bolzonella and Terranova, 2002; Nordlund and Mazur, 1994; Sarff et al., 1993). The phenomenon of phase-locking has been observed in many RFP experiments: OHTE (Tamano et al., 1987), TPE-1RM15 (Hattori et al., 1991), Reversatron II (Greene and Robertson, 1993a), MST (Almagri et al., 1992; Hokin et al., 1991), TPE-1RM20 (Brunsell et al., 1993), TPE-RX (Yagi et al., 1999), EXTRAP-T2R (Malmberg et al., 2000), RFX (Buffa et al., 1994; Zanca et al., 2001) and RFX-mod (Martini et al., 2007; Ortolani and team, 2006). The Locked Mode can rotate in the laboratory frame or *wall-lock*, depending on the properties of magnetic boundary, on modes amplitude level and on the plasma current level.

Wall locking is responsible for enhanced localized plasma wall interaction, which can induce overheating of the first wall (Valisa et al., 1997; Zanca et al., 2007a,b), anomalously large impurity influxes and radiation (Marrelli et al., 1999). Also global quantities, such as the loop voltage and fuel recycling are affected by wall locking. Techniques to mitigate these adverse wall locking effects have been successfully exploited in RFP plasmas, as will be described later on.

Fig. 4 Typical time traces of a global reconnection process, obtained by ensemble average over a large number of similar events recorded on MST plasmas. (a) relative amplitude of magnetic fluctuations; (b) toroidal magnetic flux density; (c) heat flux; (d) plasma flow and (e) ion temperature.

Depending on the experimental conditions, the core resonant dynamo modes spectra show up in the RFP in different regimes. The first, dubbed Multiple Helicity (MH) state, is characterized by the presence of many $m = 1$ Fourier components of the magnetic field at the edge of the plasma with comparable amplitude. In the second, dubbed Quasi Single Helicity (QSH) state, one single $m = 1$ Fourier component grows and becomes dominant over all the other modes, named “secondary” modes, whose amplitude is reduced with respect to that in MH.

In the MH state the overlap of the magnetic islands causes a broad region of stochastic magnetic field, where the temperature profile is observed to be flat and energy diffusion is dominated by transport in a stochastic field (Rechester and Rosenbluth, 1978).

Transient magnetic QSH states have been experimentally detected to last for several energy confinement times from 1993 in all large RFP devices (Brunsell et al., 1993; Nordlund and Mazur, 1994; Hirano et al., 1997; Sarff et al., 1997; Martini et al., 1999a; Martin, 1999). The emergence within the magnetic spectrum of a dominant mode, typically the most internally resonant one, is associated with the observed formation of a “bean”-like hot structure corresponding to the magnetic island with the same helicity of the dominant mode (Martin et al., 2000, 2002; Escande et al., 2000a; Piovesan et al., 2004a).

These states were named Double Axis (DAX) states (Puiatti et al., 2009a) as two magnetic axes are present within the plasma: the unperturbed axis-symmetric one and the axis associated with the island O-point (Lorenzini et al., 2008b). QSH states were observed to become purer and longer lasting as the plasma current was raised (in RFX-mod typically above 0.6 MA) and found to be favored by a magnetic equilibrium characterized by a slight reversal of the toroidal magnetic field at the edge (Ortolani and team, 2006; Paccagnella et al., 2006). Such a tendency was confirmed by the analysis in various RFP devices: in MST (Marrelli et al., 2002; Piovesan et al., 2004a), in TPE-RX (Piovesan et al., 2004b), in EXTRAP T2R (Frassinetti et al., 2007), and in RELAX (Ikezoe et al., 2012).

Transitions from MH to QSH can be either spontaneous or induced by external dynamic actions such as the oscillation of the edge toroidal magnetic field (OPCD technique), as demonstrated in RFX-mod (Terranova et al., 2007), or by applying a small positive pulse in the initially weakly reversed edge magnetic field (Hirano et al., 2006). The results from the RELAX device, where QSH phases lasting above 30% of the flat-top duration (Oki et al., 2012, 2013), suggest that low aspect ratio is a favorable condition for the establishment of QSH states.

The plasma current regimes above 1.2 MA explored in RFX-mod finally exhibited the predicted bifurcation towards a kink-like magnetic topology (Escande et al., 2000b), as the amplitude of the dominant mode increases and its island X-point collides with the original unperturbed axis of the configuration and separatrix expulsion occurs. This process is shown in Fig. 5a–c for a pure Single Helicity case with $m = 1$ and $n = -7$ periodicity (please note that negative toroidal mode numbers are conventionally used for modes resonant inside the reversal surface in RFX-mod) and with a fixed level of secondary modes Fig. 5d–f.

As a result of this process, a single axis remains in the plasma corresponding to the former island O-point. This new magnetic topology has been dubbed SHAX (Single Helical Axis) state, associated with a helical safety factor profile with a maximum located in the vicinity of the former separatrix.

Fig. 5 (a)–(c) Poloidal Poincaré plots of the magnetic field at increasing amplitude of the $n = -7$ mode (3%, 4% and 5%, respectively) in the SH case and (d)–(f) with a fixed level of secondary modes. The black thick lines indicate the radial extent of the good-confinement region, based on test particle simulations. In (f) sticky magnetic field lines around the helical flux surfaces are visible (note in particular the blue and pink dots). Adapted from Piovesan P, Zuin M, Alfier A, et al. (2009) Magnetic order and confinement improvement in high-current regimes of RFX-mod with MHD feedback control. *Nuclear Fusion* 49: 085036. <https://doi.org/10.1088/0029-5515/49/8/085036>

The typical time traces of a RFX-mod discharge exhibiting a long lasting transition to SHAx state is presented in Fig. 6.

The experimental behavior of these SHAx states has been particularly well reproduced by 3D MHD modeling from the Specyl code, once a small $m = 1$, $n = -7$ boundary condition with an amplitude similar to the experimental one (about 1.5% of the central magnetic field) was included in the simulations at Lundquist numbers $S = 10^7$, consistent with the experimental one (Bonfiglio et al., 2013) (see Fig. 7).

The magnetic topology change in the QSH-SHAx state is associated with a modification of the kinetic profiles. In Fig. 8 the electron temperature profiles measured by the Thomson scattering diagnostic in MH, QSH-DAx and QSH-SHAx at three time instants in the same RFX-mod discharge are shown (Marrelli et al., 2021).

The small localized hot island, typical of the DAx state is replaced by a large plateau at an electron temperature typically above 1 keV, encompassed by large gradients establishing an electron internal transport barrier (eITB), normally radially localized in the vicinity of the maximum of the safety factor profile (Puiatti et al., 2011, 2009a; Gobbin et al., 2011a,b). As a consequence, the thermal content of the plasma increases, a sign of a self-organized transition to an improved confinement regime. An almost two-fold improvement of the energy confinement time is estimated (Piovesan, 2009), as shown in Fig. 9, where this is shown as a function of the residual secondary modes amplitude, which decreases as the amplitude of the dominant mode increases.

This result has been interpreted, by means of magnetic reconstruction, as due to magnetic chaos healing. SHAx states being typically more resilient to chaos than DAx states (Escande et al., 2000b; Cappello et al., 2012; Veranda et al., 2013; Terranova et al., 2010; Gobbin et al., 2011a; Gobbin et al., 2011b).

A lower threshold of about 3–4% on the normalized amplitude of the dominant mode with respect to the edge magnetic field for the occurrence of the transition QSH-DAx/QSH-SHAx has been identified, in agreement with theoretical predictions (Escande et al., 2000c). The amplitude of secondary modes is also a relevant parameter for the appearance of wide helical structures. In particular, the lowest amplitudes of the two main secondary modes: i.e. the $m = 1$, $n = -8$ and $m = 1$, $n = -9$ in RFX-mod are associated with the widest thermal structures.

As for QSH, SHAx states are routinely obtained both spontaneously, as mentioned at plasma current above 1.2 MA (Lorenzini et al., 2009a; Bonomo et al., 2009), and triggered by a dynamic poloidal current drive, by means of the OPCD technique (Lorenzini et al., 2008b, 2009b).

Fig. 8 Electron temperature profiles as a function of normalized minor radius, r/a , in RFX-mod Quasi Single Helicity (black squares QSH-DAX, red diamonds QSH-SHAX states) and MH (blue squares) plasmas. From Marrelli L, Martin P, Puiatti ME, Sarff JS, Chapman BE, Drake JR, Escande DF, and Masamune S (2021) The reversed field pinch. *Nuclear Fusion* 61: 023001.

In the MST plasmas QSH-SHAX states appear at lower plasma current levels (around 0.5 MA) than in RFX-mod but at similar Lundquist number S , with the dominant $m = 1, n = 5$ mode, which can reach amplitudes of up to 8% of the axisymmetric field (Auriemma et al., 2011; Sarff et al., 2013; Bergerson et al., 2011).

Back-transitions from QSH-SHAX to MH states occur as a consequence of the magnetic reconnection processes associated with global rearrangements previously described.

In various RFPs, the application of a stationary or slowly rotating magnetic perturbation by means of external radial field coils proved to be effective in increasing the duration of QSH phases, both with a feedforward approach, as in MST (Evans et al., 2004; Munaretto et al., 2016, 2015), or with a feedback controlled one, as in EXTRAP-T2R and in RFX-mod (Marrelli et al., 2007). In the latter experiment, the application of a $m = 1, n = -7$ field above a given threshold in plasmas with shallow toroidal field reversal strongly improves the helical state persistence (Piovesan et al., 2011) even at higher densities ($n/n_G \approx 0.5$) than in the spontaneous case (Piovesan et al., 2013), without strong effects on the loop voltage (Gobbin et al., 2015).

The role of microturbulence as a driving mechanism of transport in the RFP has been assessed by means of gyrokinetic numerical simulations and analytical analyses. It has been proven that, due to the short field connection length in the low- q cylindrical equilibrium and the related Landau damping, the Ion Temperature Gradient (ITG) mode threshold is larger by a factor R/a than that in

Fig. 9 Energy confinement time as a function of the secondary mode amplitude in QSH_i (blue) and SHAx states (red). Adapted from Piovesan P, Zuin M, Alfier A, et al. (2009) Magnetic order and confinement improvement in high-current regimes of RFX-mod with MHD feedback control. *Nuclear Fusion* 49: 085036. <https://doi.org/10.1088/0029-5515/49/8/085036>

the Tokamak (Guo, 2008; Predebon et al., 2010a; Sattin et al., 2010). However, this threshold decreases in helical states (Predebon and Xanthopoulos, 2015) so that ITG turbulence cannot be excluded to enhance total heat transport in this condition.

In the presence of the internal transport barriers forming during the QSH-SHAx states in RFX-mod, dedicated gyrokinetic simulations showed that microtearing (MT) modes become linearly unstable. These modes have actually been experimentally observed in RFX-mod helical states, by means of highly resolved in-vessel edge probes, with spectral properties in agreement with the theoretical expectations, as shown in Fig. 10, and with amplitude well correlated with the electron temperature gradient (Zuin et al., 2013).

The occurrence of collisionless microtearing instabilities has been also studied in RFX-mod (Predebon and Sattin, 2013) and MST (Carmody et al., 2015), indicating that the high magnetic drifts in the RFP could favor such microinstabilities.

A positive isotopic effect on the confinement of SHAx states has been found by comparing hydrogen and deuterium plasmas in RFX-mod. In high plasma current regimes, characterized by the occurrence of SHAx states, the energy and particle confinement times scale as $m_i^{0.3}$ and as $m_i^{0.45}$, respectively, with a reduction of particle influx. The confinement enhancement is mainly attributed to the mitigation of transport at the plasma edge (Lorenzini et al., 2015). A 0.2 keV improvement of the electron temperature in a large part of the plasma volume has been observed in deuterium plasmas. Calculation of particle orbits confirms that the loss time in QSH regimes is about 30% higher in deuterium than in hydrogen for both spontaneous and induced helical states (Gobbin et al., 2015).

As predicted by MHD numerical simulations (Veranda et al., 2013), non internally resonant QSH $n = 6$ states (Cappello et al., 2012) can also be excited in RFX-mod, with the aim of improving the region with well conserved magnetic surfaces and reducing the magnetic field lines transport (Veranda et al., 2017, 2020). Preliminary encouraging experimental results have been obtained in RFX-mod.

Particle transport and confinement

In RFX particle diffusion coefficients of the order of $20 \text{ m}^2/\text{s}$ in the core and $5 \text{ m}^2/\text{s}$ in the edge plasma had been estimated on the basis of the observation of hollow density profiles, which imply an outward particle pinch. In RFX-mod particle diffusivity scaling with the magnetic field fluctuation in MH and QSH states (Auriemma et al., 2015) has been found to be weaker than that predicted by the Rechester-Rosenbluth theory, which suggests that, despite the magnetic field is chaotic, hidden confining structures are anyway present within the plasma (Spizzo et al., 2009). A significant improvement of particle confinement in QSH with respect to MH has been experimentally observed in TPE-RX (Frassinetti et al., 2006) and in RFX-mod, where, thanks to pellet injection in the hot region of a SHAx state, an enhancement of up a factor 3 has been estimated for the particle confinement time (Terranova et al., 2010). These results are in agreement with dedicated simulations (Predebon et al., 2004).

Single particle trajectory studies indicate that in RFX-mod plasmas neoclassical diffusion coefficient is one order of magnitude larger than the classical one (Gobbin et al., 2007, 2009a,b). Moreover, the population of superbanana particles is rather low in the presence of observed helical perturbations, as the distortion decreases when moving towards the plasma edge (Gobbin et al., 2010). As a result, differently from what occurs in unoptimized stellarators, transport is proportional to the collisional frequency.

Impurity transport studies have been performed computationally (Gobbin et al., 2007) and experimentally in both MST and RFX-mod (Barbui et al., 2015, 2014; Carraro et al., 2000; Gobbin et al., 2017) and an outwardly directed pinch velocity has been estimated. Central accumulation does not occur in QSH states in RFX-mod (Carraro et al., 2009), with larger impurity diffusivity in the core than at the edge (Menmuir et al., 2010).

Fig. 10 Comparison of experimental measurements and theoretical expectations for microtearing modes in RFX-mod QSH-SHax states. For the shaded area of frame (a) the growth rates of the most unstable modes (all with microtearing parity) as a function of the wave number $k_y r_i$ are in (b), solid symbols; open symbols represent the same data set with q profile artificially flattened; the gray line is the experimental (toroidal mode number) magnetic spectrum; in (c) the gyrokinetic estimation of the microtearing spectra are exploded on the (m, n) plane along with the experimental estimate of the measured wave numbers at the edge (gray error bars). (2013) Experimental observation of microtearing modes in a toroidal fusion plasma. *Physical Review Letters* 110. <https://doi.org/10.1103/PhysRevLett.110.055002>

MHD control in the RFP

RWM control

In the past, a serious issue for the performance and the future of the RFP configuration was represented by resistive wall mode (RWM) instabilities, which strongly limited the pulse length. Early RFP experiments in the 1980s were equipped with resistive walls, characterized by wall time constants shorter than the discharge pulse length in order to study RWM dynamics. These devices include OHTE at General Atomics (Goforth et al., 1986; La Haye et al., 1988), the Reversatron at the University of Colorado (Greene and Robertson, 1993b), the HBTX-1C experiment at Culham (Alper et al., 1989) and REPUTE-I (Asakura et al., 1986a,b).

In HBTX-1C, first clear observations were obtained of non-resonant ideal kinks (RWMs) with growth rates about a factor of three times the wall time constant, in agreement with theoretical studies. Such results were later confirmed clearly by the EXTRAP T2R experiment (Brunsell et al., 2003); the observed growth time scale of the RWMs was comparable to the wall penetration time.

The first attempt at an active feedback experiment of the $(m = 1, n = 2)$ mode was reported in HBTX-1C (Alper, 1990) by means of two helically wound coils located outside the outer shell of the vessel. The active feedback of a single RWM was successful but the experiment also proved that multiple mode control would have been necessary in order to improve RFP plasma performances.

The requirements for active RWM control were determined by theoretical studies taking into account the role played by shell resistivity and distance of the boundary (Ho and Prager, 1988) and later on also that of rotational stabilization (Jiang et al., 1995; Guo et al., 1999) and nonlinear effects (Schnack and Ortolani, 1990) with the DEBS code, where also tearing modes were considered.

The action of a virtual system of helical active coils for multiple RWM control on Fourier harmonics was introduced with a feedback scheme named Mode Control, with different gains for each single mode (Paccagnella et al., 2002b); a mostly linear behavior of RWMs was also described, as confirmed by the experimental findings in EXTRAP-T2R (Brunsell et al., 2003), and RFX-mod (Bolzonella et al., 2008).

As an alternative to helical coils, a concept for RWM feedback stabilization, named the *intelligent shell* (IS), based on a set of saddle coils surrounding the plasma, was proposed by Bishop (Bishop, 1989). A set of corresponding sensors is used to feedback control the current in order to mimic a perfectly conducting shell. The limits of the IS scheme in the simultaneous control of multiple modes are due to finite number of actuators and subsequent generation of toroidal harmonics n together with toroidal sidebands (Fitzpatrick and Yu, 1999). These limits were confirmed experimentally in initial active feedback operations on EXTRAP-T2R (equipped with a matrix of 4×32 saddle coils and corresponding saddle loop sensors) (Brunsell et al., 2004).

By extending control theory techniques developed for tokamaks (Bondeson et al., 2002), a more realistic geometrical description of the coils and of the sensors was studied in (Paccagnella et al., 2002a) with a different control scheme.

In such a scheme (dubbed *Mode Control*), the feedback variables $b^{m,n}$ are the Fourier coefficients of the flux loop sensor signals b^j , while the coefficients of the Fourier decomposition of the currents into the control coils are the current harmonics $I^{m,n}$. An inverse Fourier transform of the spectrum of these $I^{m,n}$ current harmonics is applied to determine the current in each active coil (Drake et al., 2005), with a different gain for each single mode (Bolzonella et al., 2008; Martini et al., 2007).

In order to deal with the effect of sidebands aliasing, a more advanced feedback control scheme, dubbed *Clean Mode Control* (Zanca et al., 2007a,b), was developed.

Complete stabilization of the unstable RWM spectrum was achieved in EXTRAP-T2R (Brunsell et al., 2005; Drake et al., 2008) with an increase of pulse length, limited by the power supplies, of up to 90 ms (of the order of $10 \tau_w$) as shown in Fig. 11.

The same control algorithms developed for the EXTRAP-T2R device were exploited in the RFX-mod experiment, equipped with a thin copper shell (with $\tau_w = 100$ ms) and the most advanced system of coils (made of a matrix of 4×48 arrays of equally spaced coils) fully covering the plasma.

The discharge duration was prolonged by the feedback action from 150 ms to more than 300 ms, with a relevant loop voltage reduction (Paccagnella et al., 2006).

The flexibility of the RFX-mod device allows also operation as a circular (and shaped) ohmic tokamak with a toroidal field of 0.5 T. Due to the specific RFX-mod passive boundary, when $q(a) < 2$ the $m = 2, n = 1$ external ideal current-driven kink converts into a Resistive Wall Mode. The Clean Mode Control feedback algorithm was efficient in keeping the $m = 2, n = 1$ at a negligible level, despite the fact that the available number of actuators along the poloidal direction, i.e. 4, does not satisfy the stabilization criteria for such mode (Zanca et al., 2012a,b).

After the demonstration of successful multiple RWMs control, advanced issues on the topic have been dealt with in RFP devices and theoretically. Among these, it is worth mentioning the *Resonant Field Amplification*, of particular relevance as the effects of error fields, which are seed of RWM dynamics, can be significantly different during plasma operation and in vacuum conditions (Volpe et al., 2013). In particular, the phase and the amplitude of error fields from gaps in the shell, leakage flux from the iron core or lack of symmetry in toroidal coil positioning was addressed by means of actively induced both static and rotating harmonics. Resonant field amplification effects were clearly identified in good agreement with the theoretical expectations in RFX-mod.

A limited external saddle coil coverage of the plasma boundary was simulated experimentally in RFX-mod and EXTRAP T2R, exploiting the sophisticated control algorithm software and numerically with a flight simulator with interesting results (Baruzzo et al., 2012; Marchiori et al., 2012; Olofsson et al., 2012).

An analysis of the influence on the performance of the 3D passive conducting structures surrounding the plasma using the finite element electromagnetic code Cariddi and a 2D model for RFP plasma stability (MARS-F) (Liu et al., 2000; Portone et al., 2008) has been undertaken at RFX-mod (Villone et al., 2008). A full dynamic flight simulator, including the features of the CarMa (Liu et al., 2000) code and a model of the RFX-mod control system (Marchiori et al., 2012), was developed to simulate experimental conditions.

Tearing modes control

One of the main issues for high performance RFPs is the mitigation of wall and phase locking of tearing modes (TM). Wall locking of $m = 1$ modes in the RFP has been modeled in (Fitzpatrick et al., 1999; Chapman et al., 2004), in order to explain the differences

Fig. 11 Time traces of EXTRAP T2R plasma pulses without (dashed line) and with active control (solid line): (a) discharge current; (b) total radial field amplitude at the sensor coil array. From Drake JR, Bolzonella T, Olofsson KEJ, Baruzzo M, et al. (2008) Reversed-field pinch contributions to resistive wall mode physics and control, in: *Proceedings of 22nd International Conference on Fusion Energy*. IAEA, p. EX P9-7.

exhibited by MST and RFX in terms of the current threshold for this phenomenon, by balancing the electromagnetic torque, related to eddy currents on the first resistive conducting wall surrounding the plasma, and a viscous torque, which should tend to restore natural rotation of a mode which is not-wall locked mode.

The significantly higher resistivity of the first RFX boundary (defined by an Inconel 625 alloy vacuum vessel) (Gnesotto et al., 1995) relative to that of MST was at the origin of a significantly lower mode amplitude threshold for wall locking.

Shell gaps (necessary to allow the penetration of the vertical field) (Werley et al., 1985) or static misalignment of external coils are error fields sources which play relevant roles in the wall locking phenomenon (Fitzpatrick, 1999), as extensively confirmed in experiments using the active control systems for various RFP devices (Fitzpatrick and Zanca, 2002; Hansen et al., 1998; Frassinetti et al., 2015; Fridström et al., 2018).

In addition to wall locking, phase alignment among different TMs occurs in RFPs, (Fitzpatrick, 1999) due to the electromagnetic torques (Fitzpatrick, 1999; Fitzpatrick and Zanca, 2002; Guo and Chu, 2004; Hegna, 1996) from three-wave nonlinear coupling among $(1,n)$, $(1,n+1)$ and $(0,1)$ modes.

In RFX-mod, a significant mitigation of the effects of wall locked tearing modes was achieved thanks to the active feedback by saddle coils. A relevant role in determining the success of the control technique was the identification of the pollution in real mode amplitude estimation caused by coil sidebands.

Once clean harmonics had been obtained by a de-aliasing technique (Zanca et al., 2007a,b), the implementation in real time of the Clean Mode Control algorithm (Marrelli et al., 2007) allowed RFX-mod to reach the design current of 2 MA.

Clean Mode Control is capable of reducing the edge amplitude of each wall-locked tearing mode down to a minimum value, by properly optimizing the associated proportional gain (Zanca et al., 2007a,b), with a rotation of increasing frequency being generated by any further increase in gain.

In optimized very low plasma current (< 150 kA) experiments in RFX-mod, spontaneous tearing modes rotation was observed (Innocente et al., 2014), as shown in Fig. 12, and the typical hysteresis found in other RFPs on the locking-unlocking current threshold was found to be removed by the action of the Clean Mode Control algorithm.

Tearing mode rotation under Clean Mode Control was initially described by a stationary model (Zanca et al., 2007a,b) based on the same equations for single TM wall locking (Fitzpatrick and Zanca, 2002) and more recently by a time dependent approach including nonlinear phase coupling among multiple $m = 1$ tearing modes. In this code, dubbed RFXLocking (Zanca, 2009), mode edge amplitudes and phases are evolved under the action of the feedback coils, while the mode amplitudes at the resonant surface are estimated from the experimental measurements at the plasma edge. By also implementing in the code the multiple-shell structure of RFX-mod with a model-based approach (Piron et al., 2010), the optimal gain set was obtained in order to drive the edge radial magnetic field amplitude of each tearing mode to the lowest possible value. Indeed, the RFXLocking code shows that the edge radial field, because of a physical limit coming from the plasma-shell proximity, cannot be reduced below a minimum value.

Based on the interplay between tearing modes and passive conducting boundaries in an RFP, an upgrade of the RFX-mod machine assembly has been proposed, designed and is presently under implementation. The new version of the device, dubbed RFX-mod2 (Zuin et al., 2017; (Marrelli et al., 2019b; Peruzzo et al., 2017, 2019) will aim to explore RFP plasmas with a reduced saturated level of tearing modes, and the associated magnetic chaos, thanks to an improved plasma-shell proximity. This will be obtained in RFX-mod2 by removing the stainless steel vacuum vessel so that the copper shell will become the first conducting surface for the plasma, without modification of the existing magnetic coil system.

Fig. 12 Time traces for a low plasma current discharge in RFX-mod. (a) Plasma current (black line) and $m = 1$, $n = -8$ mode toroidal field harmonic amplitude (green line); (b) spectrogram of the mode frequency (the light green line is the estimated time behaviour). Red arrow indicates the time instant at which mode unlocking occurs. From Zuin M, Dal Bello S, Marrelli L, Puiatti ME, et al. (2017). Overview of the RFX-mod fusion science activity. *Nuclear Fusion* 57: 102012. <https://doi.org/10.1088/1741-4326/aa61cc>

The 3D nonlinear MHD Specyl code, including realistic boundary conditions, envisages a 30% reduction of the energy of unstable modes (Marrelli et al., 2019a), and model simulations by the RFXlocking code indicate a threefold reduction of the last closed magnetic surface deformation with respect to that of RFX-mod (Zuin et al., 2017), see Fig. 13.

Energetic ion confinement and stability

Thanks to the exploitation of its 1 MW NBI, interesting properties of fast ion behavior have been characterized in the MST device. Tangential injection is performed of 25 keV (40 A), H or D neutrals with pulse duration ≤ 20 ms; the “beam blip” technique is exploited for the estimation of the fast ions confinement, by measuring the decay in d-d fusion neutron emission (Fiksel et al., 2005). A neutral particle analyzer is devoted to the analysis of the dynamics of D and H energy distribution functions, and their role in determining energetic particle driven instabilities (Eilerman et al., 2012).

The energetic ion confinement time turns out to be an order of magnitude larger than that of thermal ions and consistent with classical slowing down (~ 20 ms) (Fiksel et al., 2005), (Bonofiglio et al., 2019).

This result is due to the drift of fast ions around the magnetic field lines, which implies that they do not experience magnetic field stochasticity, even in MH regimes. The safety factor in the phase space associated with fast particle motion turns out to be larger than the magnetic safety factor, so that it is not characterized by the resonance of the dominant core mode, while secondary mode islands superposition is reduced along with the associated stochasticity (Fiksel et al., 2005).

During NBI injection, both energetic particle modes (EPM) (Koliner et al., 2012) and magnetic-island-induced Alfvén eigenmodes (MIAE) (Anderson et al., 2013; Cook et al., 2016) are observed to be triggered (Lin et al., 2013). Measurements of density and magnetic field fluctuations by means of an interferometer-polarimeter show that energetic particle driven modes are nonlinearly coupled and induce a flattening of the fast ion profile, which has been modeled with the NUBEAM module in the TRANSP code (Budny et al., 1992; Waksman et al., 2012). The onset of EPM activity occurs for a critical gradient in the fast ion beta (Capecchi et al., 2019) and induces fast ions redistribution towards larger values of the minor radius where they are subject to stochastic transport (Bonofiglio et al., 2019; Capecchi et al., 2019). It is interesting to add that normalized gyro-radius of the 25 keV fast ions in MST ($B < 0.5$ T) is close to that of alpha particles in a reactor plasma with $B \sim 5$ T and that the central $\beta_{fi} \sim 8\%$ produced in the MST plasmas is comparable to β_a expected in a reactor one.

It is, moreover, worth mentioning that Alfvén eigenmodes have been also detected in ohmically heated RFP plasmas (i.e. without any external source of fast particles) in the RFX-mod discharges. These modes have been interpreted as global Alfvén modes (GAE) occurring around a minimum of the shear-Alfvén continuum at the plasma edge, with an amplitude raising during global reconnection phenomena (Spagnolo et al., 2011).

A stabilizing effect of the NBI particle population on core resonant tearing mode has been described (Anderson et al., 2013; Cai et al., 2015), which makes the MH to QSH states transition less frequent. On the other hand, NBI injection during QSH states produces, because of the helical distortion, a fast ion population distributed over a larger region in the core, which makes the stochastic transport region more effective around midradius. However, classical fast ion confinement is recovered if secondary modes are reduced (Bonofiglio et al., 2019).

From Zuin M, Dal Bello S, Marrelli L, Puiatti ME, et al. (2017) Overview of the RFX-mod fusion science activity. *Nuclear Fusion* 57: 102012. <https://doi.org/10.1088/1741-4326/aa61cc>

Inductive current drive and profile control

Tearing instabilities, whose action in helically deforming the current pattern sustains the RFP configuration, results from an electric field, which peaks towards the plasma axis. This stimulated the idea that adding current drive in the outer plasma region would allow the possibility that a self-consistent current profile would develop with no need of tearing action. Various techniques have been proposed for current profile control: current induction by means of external field coils, insertable polarized electrodes, and edge-localized Radio Frequency (RF) current drive.

Among these, the most successful has proven to be the inductive approach, as it has been demonstrated to lead to strong reduction of tearing activity and of the associated magnetic stochasticity. Consequently, the energy confinement of the RFP plasmas largely improves under these conditions.

The possibility to significantly reduce (or even suppress) tearing fluctuations with an active modification of the current profile is confirmed by MHD computations (Ho, 1991; Sovinec, 1995; Sovinec and Prager, 1999; Prager, 1999). An example of the results obtained with the DEBS code is shown in Fig. 14, where the profiles of the current parallel to B are presented in both a standard (steady state toroidal induction) RFP plasma (blue curve) and with the action of dynamic active current profile control (red curve). A dramatic change in the core-resonant tearing modes amplitude occurs, which drives a relevant stochasticity reduction, as clearly visible in the Poincaré plots in Fig. 14b and c.

Inductive profile control has been approached with a range of combinations of temporal variations of the toroidal and poloidal magnetic fields. The Pulsed Poloidal (or Parallel) Current Drive (PPCD) technique entails a fast ramp down of the toroidal magnetic field, while the Self-Similar Current Decay (SSCD) involves a ramp down of both fields. The Oscillating Poloidal Current Drive (OPCD) relies on oscillation of the toroidal magnetic field, and the Oscillating Field Current Drive (OFCD) incorporates an oscillation of both fields. The two latter techniques can be applied almost continuously, while the former two only transiently.

Among these, the PPCD is the most experimentally developed. It was first studied on MST (Sarff et al., 1994) and, as mentioned, by modelling with the DEBS code (Sovinec, 1995; Svidzinski and Prager, 2007; Reynolds et al., 2008).

An example of the behavior of a MST plasma with PPCD is given in Fig. 15, where the time traces are shown of the poloidal and toroidal components of the electric and magnetic fields at the edge, $E_\theta(a)$, $E_\phi(a)$, $B_\theta(a)$ and $B_\phi(a)$ respectively, along with that of the parallel electric field $E_{||}(a) = E \cdot B/B^2$. In order to obtain an $m = 1$ and $m = 0$ reduction, along with the non-coincidence with spontaneous reconnection processes (Chapman et al., 2002), $E_{||} \geq 0$ is required, which is obtained initially by a B_ϕ ramp down. The action is prolonged by an induced E_ϕ reversal. The technique drives the reversal equilibrium parameter, F , to largely negative values (around -2). The best plasma performances with the PPCD technique have been obtained at low density with good conditioning of the plasma-facing components and good control of the magnetic boundary (Sarff et al., 1995; Chapman et al., 2002; Frassinetti et al., 2003, 2004, 2005c).

During PPCD the μ profile ($\mu = -\mu_0 a J_{||}/B$) is more peaked in the center of the plasma, which has also been observed in MHD modeling of PPCD plasmas in RFX with the SpeCyl code (Puiatti et al., 2003) and decreases at the edge as experimentally measured in MST (Chapman et al., 2000), so that the electric field in the parallel Ohm's law is approximately equal to the resistive current terms $\eta_{neo} J_{||}$ over the whole plasma (i.e. the plasma is indeed almost dynamo free) (Anderson et al., 2004, 2005).

Fig. 14 Results of MHD simulations with the DEBS code: (a) comparison of the $J_{||}/B$ radial profile in the standard steady toroidal induction case (blue) and controlled case (red). Magenta curve is an auxiliary ad-hoc parallel electron force. Poincaré plot of magnetic field line in controlled (b) and standard (c) conditions. Adapted from Prager SC (1999) *Dynamo and anomalous transport in the reversed field pinch. Plasma Physics and Controlled Fusion* 41: A129. <https://doi.org/10.1088/0741-3335/41/3A/008>

Fig. 15 Time evolution of a MST 500 kA plasma with PPCD: (a) poloidal and (b) toroidal electric fields, (c) poloidal and (d) toroidal magnetic fields and (e) parallel electric field. PPCD starts at 8.5 ms. From Chapman BE, Almagri AF, Anderson JK, Biewer TM, et al. (2002) High confinement plasmas in the Madison Symmetric Torus reversed-field pinch. *Physics of Plasmas* (1994-present) 9: 2061–2068. <https://doi.org/10.1063/1.1456930>

As a consequence, a relevant broadband reduction of higher- n modes is induced (Sarff et al., 2003a,b) as measured in MST both at the edge and in the core (Ding et al., 2003; Terry et al., 2004).

Higher-frequency magnetic turbulence is also affected, becoming less intermittent (Marrelli et al., 2005; Frassinetti et al., 2007b).

The reduction in core-resonant tearing modes has tremendous consequences on the magnetic topology, and two distinct (i.e. not overlapping) islands associated with the two innermost resonant modes have been clearly detected by tomographic X-ray measurements (Franz et al., 2004, 2006), a clear sign of decreased stochasticity.

A more ordered magnetic topology is confirmed by the detection of runaway electrons in the core of MST plasmas (O’Connell et al., 2003), normally prevented in RFP plasmas with stochastic magnetic field.

The reduced stochasticity with PPCD leads to a global improvement of the plasma performance in various RFPs (Martini et al., 1999b; Chapman et al., 2001; Yagi et al., 2002; Cecconello et al., 2003).

This improvement includes a better confinement of energetic electron and ion particles, of thermal electron particle, larger values of the electron density in terms of Greenwald fraction, record values of electron and ion temperature for a RFP. These are accompanied by a reduction of the loop voltage necessary to sustain the discharge (and hence of the Ohmic heating power) and beta values exceeding the Mercier criterion along with classical confinement of impurity ions.

Global particle confinement time improves eight-fold in MST (Lanier et al., 2000, 2001), while the particle diffusion rate drops by about a factor of two in RFX plasmas (Puiatti et al., 2003). In TPE-RX a fivefold improvement in the global particle confinement time (Koguchi et al., 2006) is estimated when pellets are injected during PPCD. This technique allows access to regimes with improved confinement at higher density in PPCD plasmas (Lorenzini et al., 2002; Puiatti et al., 2003; Koguchi et al., 2006), even above the Greenwald density limit (Wyman et al., 2008, 2009; Chapman et al., 2009; Caspary, 2014; Sarff et al., 2015).

An improvement of impurity ions confinement also occurs with PPCD; in RFX the core region of lower diffusivity is expanded from the outer 10% of the plasma in steady condition to 20% with PPCD (Carraro et al., 2002), while in EXTRAP T2R, diffusion decrease by about a factor of two in the core was estimated (Kuldkepp et al., 2006). In MST, impurity transport decreases to the classical value (Kumar et al., 2012a,b; Barbui et al., 2014). Impurity ions drifts are not dominated by neoclassical effects and the ions experience an outward convection, so that the impurity density profile and the Z_{eff} profile (Galante et al., 2015) become hollow.

A significant increase in the central electron temperature is typically found (Sarff et al., 1997; Stoneking et al., 1998; Bartiromo et al., 1999; Chapman et al., 2001; Cravotta et al., 2003; Yagi et al., 2003), with central $T_e \sim 2$ keV in MST. On the other hand, only a small effect is observed on ion temperature dynamics (Chapman et al., 2002) during PPCD in low density plasmas, but, interestingly, the ion heating coming from magnetic energy conversion during global reconnection processes is trapped in the plasma if such events are triggered shortly before PPCD starts, with a ten-fold increase of the ion energy confinement time.

When PPCD is applied in higher density plasmas in combination with pellet injection, an ion temperature increase is measured in MST (Wyman et al., 2008) as a consequence of the increased ion-electron collision rate and the larger input Ohmic power required for the sustainment of the discharge.

The energy confinement time doubles in RFX and EXTRAP T2R (Martini et al., 1999b; Cecconello et al., 2003), while in TPE-RX a five-fold increase was estimated (Yagi et al., 2003; Frassinetti et al., 2007a) and a ten-fold increase in MST, which exhibits τ_E up to 12 ms (Chapman et al., 2009, 2010). The MST values are not far from tokamak-like (Sarff et al., 2003a,b; Chapman et al., 2010), as

can be deduced by Fig. 16 where data from MST standard and PPCD discharges are compared to the tokamak reference with the same plasma size, magnetic field strength, and heating power as predicted by the IPB98(y,2) ELMY H-mode tokamak confinement scaling (ITER Physics Expert Group on Confin., 1999).

Obviously, the tokamak scaling does not apply to the RFP case, but it is interesting to observe that the best RFP energy confinement is comparable to that expected for a tokamak plasma with the same size and magnetic field.

The improved confinement and the reduction of fluctuations due to tearing modes in PPCD plasmas is accompanied by a relevant modification of the properties of the high frequency (> 10 kHz) component of the fluctuation spectra. In particular, density-gradient-driven trapped electron modes (TEM) have been identified in MST at $k_{\perp} \rho_i \approx 0.1 - 0.2$, where $k_{\perp}$ is the perpendicular wavenumbers and ρ_i the ion Larmor-radius, propagating in the electron diamagnetic drift (Duff et al., 2018). These modes are destabilized due to a density profile overpassing a critical gradient threshold $R/L_n \approx 20$, where L_n is the local density gradient scale length, $L_n \equiv n_e(r)/|\nabla n_e|$, as shown in Fig. 17. The results are in agreement with the predictions of linear gyrokinetic modeling by the GENE code (Carmody et al., 2015; Terry et al., 2015).

As mentioned, in addition to PPCD, various inductive current profile control techniques have been proposed and studied experimentally on RFP devices.

The Self-Similar Current Decay (SSCD) (Watterson and Gimblett, 1983; Caramana and Nebel, 1988) entails a self-similar temporal ramp-down of both B_{θ} and B_{ϕ} to produce an inductive electric field due to the magnetic flux decay which sustains the current with $E_{\parallel} = \eta J_{\parallel}$ (no dynamo) with a MHD stable current profile (Nebel et al., 2002). SSCD discharges in RFX-mod exhibit magnetic fluctuations drop, a 50% increase of the poloidal beta, ($\beta_p = 2\mu_0 \langle p \rangle / B_{\theta}^2 a$), and of the global energy confinement time (Zanca, 2007). First, non-optimized, attempts on MST suggest a three-fold increase of the energy confinement time. The SSCD technique is planned to be more deeply and extensively investigated in the RFX-mod2 device.

The quasi-steady Oscillating Poloidal Current Drive (OPCD), which entails oscillation of the toroidal magnetic field, was tested in both RFX (Bartirromo et al., 1999; Bolzonella et al., 2001; Carraro et al., 2002) and RFX-mod (Terranova et al., 2007). In OPCD plasmas during the PPCD-like phase (i.e. phase of decreasing reversal parameter, F), robust transitions to Quasi Single Helicity States occurred, as already mentioned. Helical electron temperature structures emerged, with global energy confinement time increasing by about 60% (Terranova et al., 2007), which is, anyway, lower than the one estimated during the spontaneous SHAx states.

Among the inductive current drive techniques, the Oscillating Field Current Drive (OFCD), which entails oscillation of both B_{θ} and B_{ϕ} fields, is the one with interesting implications for a RFP based fusion reactor as it opens the possibility of a steady-state sustainment scenario. In particular, in OFCD, oscillatory toroidal and poloidal loop voltages are applied, and the nonlinear self-organization process operating in RFP plasmas generates a dc current. In principle, the plasma current can be indefinitely sustained by zero time-average loop voltages, without the need for a gradual increase in the net magnetizing flux applied.

Nonlinear visco-resistive MHD modeling of RFP plasmas gives the theoretical basis for OFCD operation, passing through the principle of a relaxed state, where the magnetic energy is minimized with the conservation of the total magnetic helicity, K , constraint.

In PPCD plasmas (red points) TEM emerge above a critical-gradient threshold close to that predicted by GENE. From Duff JR, Williams ZR, Brower DL, Chapman BE, et al. (2018) Observation of trapped-electron-mode microturbulence in reversed field pinch plasmas. *Physics of Plasmas* 25: 010701. <https://doi.org/10.1063/1.5010198>.

If both toroidal and poloidal loop voltages are sinusoidal at a given frequency, then net helicity injection, averaged over a cycle, is possible and maximized for a phase shift $\delta = \pi/2$. The frequency, must be greater than the inverse resistive diffusion time, $\tau_R^{-1} = \eta/\mu_0 a^2$, but lower than the typical time scale of magnetic relaxation for the RFP, i.e. the resistive-Alfvénic hybrid timescale ($\sqrt{\tau_R \tau_A}$), typically in the audio frequency range.

A demonstration of full current sustainment by OFCD in present experiments is not feasible due to the relatively low Lundquist number. 3D, nonlinear, resistive MHD modelling (DEBS code) was used to study the effect of OFCD at moderate $S = 10^5$ in conditions with a large AC ripple (Ebrahimi et al., 2003).

The first OFCD tests were performed on the ZT-40M device (Schoenberg et al., 1988). An extensive experimental analysis has been devoted to the OFCD technique on the MST device over a range of plasma current. The OFCD drive and anti-drive results from MST are shown in Fig. 18 (McCollam et al., 2006), where a continuous current ramp-up during the flat-top of the discharge is induced in the former case. On the basis of the experimental results, a limit of 15% of the total current is estimated to be drivable by OFCD. The maximum OFCD-driven current in MST plasmas occurs for oscillator phasing $\delta = \pi/8$ and not $\delta = \pi/2$, as expected for a global helicity balance, which has been interpreted as being due to an increase in the dissipation of magnetic helicity (McCollam et al., 2010), related to the dynamics associated with relaxation and confinement.

Nevertheless, the good agreement between the simulations and experiment suggests a robust physics basis for OFCD and further tests of OFCD in RFP plasmas with larger size and temperature, i.e., at larger Lundquist number, are envisaged to be performed in the RFX-mod2 device, presently under development. In particular, in high Lundquist number RFP plasmas, the efficacy of OFCD in the quasi-single-helicity (QSH) regime typical of such conditions needs to be verified.

Plasma-wall interactions issues

In the RFP the magnetic topology strongly influences the plasma-wall-interaction (PWI). The locked mode, due to nonlinear tearing mode interactions, produces deformations of the last closed magnetic surface, which can induce strongly local power deposition on the first wall, leading to uncontrolled release of both main fuel and impurities. An example is shown in Fig. 19, where the image taken from a CCD internal camera is compared to the reconstruction of the magnetic perturbation for a RFX-mod discharge.

In RFX-mod the tearing mode mitigation by the active control system previously discussed allowed a much more uniform PWI to be obtained, compared to that of the previous RFX, while in the EXTRAP T2R active feedback control allowed an improvement of the performance (Brunsell et al., 2004).

In the RFX-mod the helical ripple of QSH states modulates the plasma edge, so that the PWI is distributed over a helical region much larger than in the MH state, with a helical modulation of edge plasma parameters also found (Scarin et al., 2011, 2019). The helically deposited power density is $\approx 5 \text{ MW/m}^2$ even at the highest current (Puiatti et al., 2013b), with plasma radiation more symmetric than in MH (Spizzo et al., 2001). However, even in the purest QSH, the phase locking of the secondary modes induces a residual PWI, which it is planned to avoid in the next RFX-mod2 device (Scarin et al., 2019).

PWI is of particular relevance in devices with a carbon wall, such as RFX-mod, as the plasma density level of the discharge is mainly determined by wall desorption, with a recycling coefficient R greater than 1, rather than controlled by the fueling (Bergsäter et al., 1995; Puiatti et al., 2013a).

With the aim of avoiding a strong (uncontrolled) release of particles in high current discharges, a wide range of wall conditioning treatments are routinely applied in the various RFPs. These include Glow Discharge Cleaning (GDC), Pulse Discharge Cleaning, boronization, lithization, hot wall operations (Bergsäter et al., 1997; Canton et al., 2013). As an example, the positive effects of boronization obtained in MST include prolonged phases without discrete reconnection events, because of a lower plasma resistivity, and a factor of 3 increase of the energy confinement time (Chapman et al., 1996).

Fig. 19 (left) image taken with a CCD camera, where the footprint of the perturbation associated with the Locked Mode in a RFX-mod discharge is clearly visible; (right) magnetic reconstruction of the perturbation. Colors refer to the distance between the non-axisymmetric plasma and the wall, ranging from blue (furthest) to red (closest). Adapted from Martini S, Agostini M, Alessi C, Alfier A, et al. (2007) Active MHD control at high currents in RFX-mod. *Nuclear Fusion* 47: 783. <https://doi.org/10.1088/0029-5515/47/8/008>

Lithization, implemented in RFX-mod by a lithium capillary-pore system (Puiatti et al., 2013b) and lithium pellet injection (Munaretto et al., 2015; Innocente et al., 2015) induces significant decrease of oxygen and carbon influxes, improvement of density control, a slight peaking of density profiles, though a clear confinement improvement has not been observed.

As described previously, a close fitting conducting wall is mandatory in RFPs. For this reason, present RFPs are not equipped with divertors, which would, in any case, present additional difficulties due to the non-stationarity and non-uniformity of the edge topology. The feasibility of a pumped limiter as an alternative to a divertor has been proposed (Sonato et al., 2002), but not yet experimentally applied.

However, the similarity of the 3D field structures of RFPs and stellarators suggests the possibility of exploiting the coil system to induce a magnetic configuration (Martines et al., 2010) resembling the island divertor of the Stellarator (Konig et al., 2002). This concept would rely on the chain of $m = 0$ magnetic islands that develop at the reversal surface with the same helicity as the dominant mode in QSH-SHAX states. The X-points of $m = 0$ islands, which would need to be actively controlled, would act as the X-point of a divertor with localized plates.

Density and β limit

In the RFP both low and high density limits characterize the operational parameter space. The lower limit is posed by the generation of runaway electrons and the growth of magnetic fluctuations. As the purest and longest helical states are found in low density conditions, this regime has been extended due to the exploitation and optimization of the Clean Mode Control feedback system (Gobbin et al., 2015). The upper density limit was compared to the Greenwald limit (Greenwald, 2002) in both RFX-mod (Valisa et al., 2004) and MST standard plasmas (Wyman et al., 2009). Indeed, the RFP is found to exhibit an empirical limit, that somehow resembles that of tokamaks, being related to the current density, which, as already mentioned, can be very large in RFPs.

Recently, a power balance model accounting for neutrals and impurity radiation has been developed, which successfully describes density limits in the stellarator, RFP and L-mode (low confinement mode) tokamak (Zanca et al., 2017, 2019).

In the RFX-mod discharges at values close to the Greenwald value, a temperature decrease is measured together with a density accumulation at the edge (Spizzo et al., 2010). For densities above a critical value, $n/n_G \approx 0.35$, a back transition from the QSH to the MH regime occurs (Scarin et al., 2011). A poloidal radiating belt forms (Valisa et al., 2004; Puiatti et al., 2009c), with similarities with the highly radiating MARFE in tokamaks (Lipschultz, 1987) or Serpens in the LHD stellarator (Miyazawa et al., 2006).

It is important to note that the density limit is not a disruptive one in the RFP, but that normally only a soft decrease of plasma current occurs. Indeed, in the RFP, when the density increases, the plasma cools, so that resistivity increases along with the loop voltage, i.e. the input ohmic power necessary to sustain the discharge (Spizzo et al., 2010).

The role played by the $m = 0$ mode magnetic topology, associated with the maximum deformation due to the locking in phase of $m = 1$ modes, in determining density accumulation and hence the density limit has been the focus of dedicated experimental campaigns in RFX-mod (Spizzo et al., 2012), (Spizzo et al., 2015). This is summarized in Fig. 20, where the maximum H_α light emission can be correlated with the $m = 1$ mode deformation, (green and red lines in panel (d)), thanks to the application

Fig. 20 A high density, $n/n_G = 0.8$, RFX-mod discharge: (a) plasma flow as a function of the normalized toroidal angle, $\phi - \phi_{\text{lock}}$ and Poincaré plot of the $m = 0, n = 1$ island; (b) tomographic map of total radiation; (c) map of electron density; (d) H_α emissivity (solid) and $m = 1$ deformation (dashed). The stagnation point for the plasma flow corresponds to the X-point of the island and to the maximum radiation and density. The reversal surface, i.e. where $B_\phi = 0$, is indicated by a dashed, horizontal line in panels (a)–(c). From Spizzo G, Agostini M, Scarin P, Vianello N, et al. (2012) Edge topology and flows in the reversed-field pinch. *Nuclear Fusion* 52: 054015. <https://doi.org/10.1088/0029-5515/52/5/054015>

of an upgraded version of the guiding-center code ORBIT (White and Chance, 1984), including the effect of a recycling wall (Spizzo et al., 2012).

In RFP plasmas $n/n_G > 1$ regimes have been produced in several conditions. In RFX-mod, the Greenwald value has often been exceeded at low current levels (≤ 0.3 MA) (Spizzo et al., 2015), when the amount of available loop voltage, due to the input ohmic power limit, is maximum. Moreover, helium plasmas favour $n/n_G > 1$ conditions (Valisa et al., 2004; De Masi et al., 2012).

In MST, $n/n_G = 1.4$ ($n_e = 0.9 \cdot 10^{20} \text{ m}^{-3}$) has been obtained by exploiting cryogenic pellet injection during PPCD phases (Sarff et al., 2015; Wyman et al., 2009).

No disruptive β limit exists for the RFP, but a “soft” degradation of confinement is observed, likely when pressure driven emerges during improved confinement regimes induced by active current profile control (Wyman et al., 2009).

Experimentally, high beta values of up to $\beta_p \approx 18\%$ had been obtained in the TPE-1RM20 RFP with a reduction of magnetic fluctuation associated with the dynamo activity (Hirano et al., 1996) and in TPE-RX as a result of fast gas puffing (Sakakita et al., 2004). Also in RFX-mod, the highest poloidal beta values of $\approx 15\%$ have been observed when n/n_G approaches 1 (Innocente et al., 2007), while a small degradation of β_p with increasing plasma current and a more significant increase as n/n_G raises is predicted by statistical analysis (Innocente et al., 2009). In MST, a modest decrease of β_p with increasing current was reported (Stoneking et al., 1998), while 3D resistive MHD simulations by the DEBSP code, based on stochastic transport scaling (Scheffel and Schnack, 2000), predict a dependence of β_p on I_p which is stronger than the experimental RFX-mod findings.

In various RFP devices record values of transient β enhancement were achieved by applying current profile techniques in high-density plasmas, as, for example, in RFX, where a 50% β_p increase was induced by Oscillating Poloidal Current Drive (Martini et al., 1999a). In TPE-RX and MST, PPCD leads to an enhancement of β_p by up to a factor of 2 (Sarff et al., 2003a), while record values were measured when during PPCD phases in which deuterium pellets were injected (Chapman et al., 2009; Koguchi et al., 2009).

By optimizing the pellet parameters in MST, pressure gradients exceeding the Mercier limit have been produced (Wyman et al., 2009; Chapman et al., 2009), corresponding to a value of $\beta_p \approx 40\%$. In such regimes both pressure-driven interchange modes and tearing modes are predicted to be linearly unstable (Chapman et al., 2009). Interchange modes have not been observed in MST, while in RFX-mod the observation of edge magnetic fluctuations, which correspond to linearly unstable pressure driven modes with tearing parity, has been reported (Zuin et al., 2010).

Neoclassical bootstrap current at high β

In an axisymmetric RFP, the fraction of trapped particles in the core is similar to that in a tokamak with the same aspect ratio, while it falls to lower values at the edge, depending on the current profile (Stoneking et al., 1998). Due to the higher poloidal field, the corresponding bootstrap current is much lower than in tokamaks (Gobbin et al., 2009a; Zanca and Terranova, 2004; Guazzotto et al., 2004). In present day circular RFPs the bootstrap mechanism can provide only a negligible additional current (Guazzotto and Paccagnella, 2009). In RFP Quasi Single Helicity states, because of the additional helical field ripple, a modest increase of the bootstrap current is envisaged (Gobbin et al., 2009a), which could only be slightly improved by shaping effects (Guo et al., 2013).

The situation is considerably different in low aspect ratio RFP equilibria, due to neoclassical viscosity enhancement (Sanpei et al., 2009). In a reactor relevant regime, with an aspect ratio of 2, with appropriate shaping it is predicted that an equilibrium with 94% bootstrap current and $\beta = 63\%$ which is stable to ideal kinks and Mercier localized modes could be sustained (Shiina et al., 2005).

Acknowledgments

This chapter is dedicated to the memory of the friend and brilliant physicist Paolo Piovesan. The Author thanks the whole EXTRAP-T2, MST, RELAX, and RFX teams and in particular M.E. Puiatti, L. Marrelli, and P. Martin for their invaluable support.

Glossary

Breeding blanket It is the region surrounding the fusion reactor core. The blanket of a fusion reactor has the threefold purpose of breeding the tritium by interactions of the fusion neutrons with lithium, of converting the energy of the neutrons to high-grade heat for electricity generation, and of shielding the super-conducting magnets from energy deposition and radiation damage.

Cable-in-conduit conductor Current carrying element made by a cable surrounded by a metallic jacket.

Cassette body (divertor) A cassette body (made of stainless steel in ITER) mechanically supports and feeds coolant to the divertor plasma facing components (PFCs). The entire cassette assembly must be capable of withstanding the thermal loads

*Currently on assignment to EUROfusion.

from the plasma and from the neutron flux, and the loads generated by electromagnetic forces. Also, it performs the function of neutron shielding.

Critical heat flux The heat flux limit at the cooling circuit inner wall at which the onset of a phase change (boiling) of coolant occurs forming a layer of bubbles covering the wall surface and thus causing a severe damage of the overheated wall material due to hindered heat transfer.

Central solenoid coils Components of a tokamak that produce inductive magnetic flux to ramp up and maintain the plasma current and contribute to shape the plasma.

Correction coils Components of a tokamak that correct magnetic field errors.

DEMO Acronym for Demonstration Reactor. The requirements vary from nation to nation. In Europe the main aims of DEMO are to demonstrate the production of few hundred MWs of net electricity, the feasibility of operation with a closed-tritium fuel cycle, and maintenance systems capable of achieving adequate plant availability.

Divertor Component of a magnetically confined toroidal fusion device that diverts charged particles on the outer edge of the plasma into a separate chamber where they strike a barrier and become neutralized. In a reactor, the divertor would incorporate a system for pumping out the neutralized particles as exhaust from the machine. A divertor, like a limiter, prevents the particles (including helium ash) from striking and degrading the chamber walls and dislodging secondary particles that would cool and contaminate the plasma.

Double pancake Methodology for winding the conductor.

First wall Innermost shield of the main vessel wall of a fusion reactor. It forms the plasma-facing liner of the blanket structure and protects the underlying steel structure from hot plasma.

High-heat-flux Heat fluxes expected for the plasma-facing components in a fusion reactor typically ranging from a few MW/m² to several tens MW/m².

High temperature superconductors Superconducting materials with a critical temperature above the liquid nitrogen temperature (77 K).

In-vessel components Components installed inside the vacuum vessel of a fusion reactor. Divertor, blanket, pumping systems, port plugs and diagnostic sensors belong to this category.

ISI In-service inspection. Regular inspections of the reactor pressure vessel to verify that no damage has occurred.

Limiter Structures placed in contact with the edge of a confined plasma, which are used to define the shape of the outermost magnetic surface (see entry for LCFS). See also entry for divertor.

Low temperature superconductors Superconducting materials with a critical temperature lower than 20 K. The term generally refers to Nb-based superconductors that were already in use prior to the discovery of HTS.

Plasma-facing components In-vessel components mounted onto the vessel and facing plasma or standing in direct contact with plasma: first wall and divertor.

Poloidal field coils Components of a tokamak that assist in shaping and stabilizing the plasma.

Radial plates Thick steel plates to embed the insulated superconductors in a magnet winding.

React&Wind Manufacturing approach for Nb₃Sn coils.

Scrape-off layer Plasma edge layer outside the boundary separating those magnetic field lines that intersect the wall (open lines) from the closed field lines that never intersect the wall (closed lines).

Toroidal field coils Components of a tokamak that assist in stabilizing the plasma, by creating a “magnetic bottle” for confinement.

Vacuum vessel The vacuum vessel maintains a high vacuum/low impurity volume for the production of the plasma. In a reactor it also acts as a first confinement barrier for tritium and contributes to limiting the heat flux to the toroidal field coils.

Wind&React Manufacturing approach for Nb₃Sn coils.

Winding pack Region of the cross-section of a magnet that contains the (super)conducting cables.

Introduction

This chapter provides a brief account of the current status of the design and development of the magnetic fusion reactor core systems, such as the superconducting magnets, the divertor, the vacuum vessel and remote maintenance. Other important systems, such as the breeding blanket are not discussed here but the interested reader can consult other sources (see for example [Boccaccini, 2021](#)).

ITER technology is discussed to illustrate the current status of technology R&D toward a fusion power plant, and the DEMO studies are presented to illustrate the considerations involved and progress being made in extrapolating the technology toward the even more exacting demands of a power plant generating electricity with high availability. The main differences between ITER and DEMO and the outstanding DEMO design and technology challenges, where knowledge gaps exist, are discussed by [Federici et al. \(2014\)](#) and by [Federici et al. \(2017\)](#). In this sense, the DEMO technology can be considered as ‘prototypical’ of that used in a power plant, but with the expectation that there may be further evolution in the development of industrial scale fusion power plants.

Conceptual designs have been developed for both tokamak and stellarator approaches to a fusion power plant. Although the magnetic configurations and detailed engineering designs differ, much of the technology under development for the tokamak DEMOs currently under study is also applicable to stellarator designs. Therefore, the discussion in the chapter is focussed on the tokamak configuration, where the engineering analysis and R&D is more advanced, but the considerations are relevant to the stellarator line of development.

Conceptual tokamak power plant designs have considered both pulsed and steady-state operation of the fusion core. For the EU DEMO technology, which is discussed as prototypical of power plant technology in the present chapter, a pulsed design has been chosen to accelerate the progress to a device capable of electricity production ([Federici et al., 2019](#); [Donne, 2021](#)).

Superconducting magnets

Superconducting magnets in fusion devices

In the framework of magnetic confinement fusion, magnetic fields are used to initiate, confine, shape and control the fusion fuel in the form of [plasma](#). Most of the experimental devices built until now are toroidal machines, such as tokamaks and stellarators.

The properties, advantages and challenges of the various magnetic configurations are discussed by [Galvão and Canal \(2021\)](#).

Starting from the 1980s relevant milestones in plasma engineering were achieved in pulsed operation by devices made with copper windings, such as the Tokamak Fusion Test Reactor (TFTR) ([Meade, 1995](#)), The Joint European Torus (JET) ([Wesson, 2000](#)) and the JAERI Torus-60 (JT-60) ([Ando et al., 1988](#)). Many deuterium-tritium (D-T) experiments have been conducted on

TFTR and JET, which have produced fusion powers of 11 MW (in 1994) and 16 MW (in 1997), respectively. The JET device is still in operation to test a beryllium/tungsten plasma facing wall and new D-T experiments for ITER.

Despite evident advantages of technological maturity and low costs, copper coils cannot generate steady-state magnetic fields higher than a few Tesla in very large volumes. The need for large, reliable, high-field superconducting (SC) magnets has been recognized since the 1980s to satisfy the long-pulse or steady-state demands of power-producing devices.

The intrinsic advantage of using SC magnets is the possibility of carrying higher current and producing stronger magnetic field than conventional copper (Cu) coils. Compared to traditional technology, the use of superconductivity allows the power consumption to be reduced, even if SC coils must be cooled with supercritical helium (S-He) in the range of 4 K (-269°C). However, for large-scale reactors such as ITER or DEMO that aim to confine and shape the plasma for long burning periods, superconductivity is an essential technology (Bruzzone, 2015).

Superconducting coils are generally manufactured using low-temperature superconductors (LTS), such as niobium-titanium (NbTi) for magnetic fields up to about 6 T or niobium-tin (Nb_3Sn) for fields between about 6 T and 16 T.

In the manufacturing process of Nb_3Sn magnets a specific heat treatment (HT) is required for allowing the formation of the SC material. Since Nb_3Sn becomes brittle after the HT and experiences degradation of its performances if subject to tensile strain, the HT generally follows the winding phase of the manufacturing procedure. This is the so-called Wind&React (W&R) approach, which is used for ITER coils. However, also the React&Wind (R&W) technology is considered for the manufacture of Nb_3Sn coils. In this second approach the HT is performed before the winding, which requires extreme care in manufacturing and handling of the magnet winding. On the other hand, the R&W approach allows the reduction of the effective compressive strain acting on Nb_3Sn with a notable improvement of the SC performances.

Although there are many examples of stellarator experimental devices, in particular the Large Helical Device (Imagawa et al., 2009) in Japan and Wendelstein 7-X (Rummel et al., 2012) in Germany, which both make use of superconducting coils, most of the existing magnetic fusion devices are tokamaks. Some fusion devices implementing SC magnets are already in operation, such as Tore Supra (Equipe Tore Supra, 1989) in France, KSTAR (Kim et al., 2005; Kwon et al., 2011) in Korea and EAST (Wu and EAST team, 2007; Wei et al., 2010) in China. Other fusion devices based on superconducting Tokamaks are in construction, like JT-60SA (Yoshida et al., 2010) in Japan, and ITER (Mitchell et al., 2012) in France.

A new generation of compact tokamaks is currently under study, i.e. ARC (Sorbon et al., 2014) and SPARC (Greenwald et al., 2018), that opens an attractive path for fusion energy development through high-field (>20 T) and small-volume devices. For achieving magnetic field higher than 16 T high-temperature superconductors (HTS) are the unique enabling technology. In compact tokamaks it is expected that all coils are manufactured with HTS conductors. The long-term technological steps toward using HTS in device design will be addressed in Section “HTS superconductors.”

It is worth noting that HTS are presently used in the design of ITER current leads, which is a component of the feeders that brings current from the power supply to the magnet. In ITER the leads consist of a section of a bismuth strontium calcium copper oxide (BSCCO 2223) high temperature superconductor (HTS) and a conventional copper section connected together through an electrical joint (Ballarino et al., 2012). The joint and copper are cooled by helium gas at 50 K, the cold end of the BSCCO 2223 at 4.5 K.

Magnetic system of ITER

The magnet system of the ITER fusion reactor is presented in Fig. 1 as an example of SC magnet system in a tokamak (Mitchell et al., 2008, 2012).

The Toroidal Field (TF) coils, distributed toroidally around the vacuum vessel, produce the dominant component of the confining magnetic field. In ITER there are 18 D-shaped Nb_3Sn coils measuring $9\text{ m} \times 16.5\text{ m}$, capable of producing 41 GJ of magnetic energy and a field of 5.3 T on the plasma center. In order to achieve such a high value of magnetic field over a major radius of 6.2 m, the current flowing in the TF conductors is 68 kA, which produces a maximum magnetic field of 11.8 T on the coil. As reported in Fig. 2 (left side), each TF magnet is made by a winding pack (WP), that contains the superconducting cables, enclosed by a stainless steel casing, which is the principal structural component of the magnet system. The weight of each TF coil is about 360 t, distributed among its components: 110 t for the WP, 190 t for the casing and 60 t for pre-compression systems, shear keys and bolts.

The Central Solenoid (CS) coils produce inductive flux to ramp up and maintain the plasma current and contribute to shape the plasma. In ITER the CS is made of six independent Nb_3Sn modules, with a total height of 13 m, a diameter of 4 m and a total weight of about 1000 t. The maximum operating current in the CS modules is 45 kA, leading to a maximum field of 13 T reached in the center of the stacked modules and a magnetic energy stored in CS coils of 7 GJ. This generates a sufficient magnetic flux to allow initiating and sustaining a plasma current of 15 MA for about 400 s under burning plasma conditions.

The Poloidal Field (PF) coils control the radial position of the plasma, contributing to its stability by maintaining the clearance between the plasma and the first wall. PF magnets are also essential elements of the slow vertical position control and of the plasma shaping capability. In ITER the six annular NbTi PF coils are located outside of the TF magnet structure. They are designed to operate at a maximum current of 45 kA, which generates a maximum magnetic field of 6 T on the coils and a total magnetic energy of 4 GJ. The largest magnet has a diameter of 24 m; the heaviest is 400 t, with a total combined weight of 2163 t.

All of the coils mentioned above are toroidally symmetric. There are also asymmetric coils, namely the superconducting Correction Coils (CCs), with the role of correcting magnetic field errors (Hugué, 1997) potentially caused by deviations from target dimensions during manufacture and imprecise positioning during assembly. The concept of magnetic error fields and their impact

on plasma performance is discussed elsewhere (Lao, 2020). In ITER 18 CCs, divided into three independent sets of six coils each, will be installed around the TF magnets.

Superconducting magnet technology

Superconducting magnet technology is developed at industrial level thanks to the realization of large scale projects, such as the fusion reactors mentioned in Section “**Superconducting magnets in fusion devices,**” and high-energy accelerators, like the Large Hadron Collider (LHC) realized at CERN. However, nuclear fusion devices have certain criticalities that led to the development of specific technologies, as reported below.

Cable-in-conduit conductors

The cable-in-conduit conductor (CICC) concept is based on the observation that the cooling efficiency in a conductor is improved if S-He (at about 4.5 K) flows in the turbulent regime in direct contact with the SC strands (Muzzi et al., 2015). In nuclear fusion reactors SC magnets are subject to several sources of heat loads, such as the nuclear heat load and the thermal load coming from gravity supports. In order to maintain good magnet stability, large heat removal capabilities are required and this explains why the design of the WPs for fusion reactors mostly relies on CICCs.

In a CICC, superconducting and copper wires are cabled in a multi-stage, transposed, and twisted structure. The cable is then inserted and compacted inside a stainless steel (SS) jacket, maintaining a void fraction that guarantees the forced circulation of the refrigerating S-He. Depending on conductor size and hydraulic length, one or more spirals exchanging He with the strand bundles might be introduced in the cable as pressure relief channels.

The TF conductor of ITER is shown in Fig. 2, right side, as an example. It includes 900 Nb₃Sn SC strands and 522 Cu strands, whose role is to prevent the burning of the SC wires during the quench from the superconducting to the normal state. Each SC strand is made of thousands of SC filaments in order to reduce the AC losses that are generated in the presence of variable magnetic fields (Wilson, 1987).

The use of Nb₃Sn as superconductor allows the target field of 11.8 T for ITER TF coils to be achieved. However, in contrast to NbTi, its performance is sensitive to mechanical loads (Muzzi et al., 2012) and suffers degradation because the material is brittle after the heat treatment required for Nb₃Sn formation. In fact, during the magnet operation, the SC cable inside the jacket is mechanically loaded by high Lorentz forces of about 800 kN/m. This translates into a combination of bending strain and contact stress on the wires (Mitchell et al., 2013) that might lead to the fracture of Nb₃Sn filaments, especially in case of tensile stresses. The irreversible degradation of the SC performance occurs during repeated electromagnetic or thermal loading cycles, until stabilization is reached. The effect was observed on most of the TF short samples tested in the SULTAN facility (Breschi et al., 2012) by applying 1000 electromagnetic cycles and various warm-up/cool-down cycles.

Increasing the stiffness of the cable and reducing the void fraction can mitigate the issue, as demonstrated by qualification tests of ITER CS conductors (Martovetsky et al., 2017). However, degradation remains a critical aspect of the conductor design, that must be solved for guaranteeing the reliability of future power plants.

Radial plates

A specific feature of the ITER TF coil design is the use of thick austenitic SS radial plates (RP) to embed the insulated conductors in machined groves (Hugué, 1997). ITER is the only fusion device to date that has adopted this solution, with the aim to transfer the Lorentz forces acting on each conductor directly to the case. The RP prevent the accumulation of forces on the conductor and its turn insulation, reducing the probability of insulation degradation due to mechanical fatigue. The role of the SS jacket around the cable is therefore limited to support the local conductor forces and provide a containment for the forced flow helium. In order to manufacture the ITER TF coil (Mitchell et al., 2012), the conductor is wound in “double pancakes” (DP) making use of a mold. After the heat treatment, the mold is removed and the DP is transferred to radial plate grooves with an accuracy of a few millimeters. These operations are very complex and require special equipment to handle and move the different components. All technical issues were successfully solved in the manufacturing phase, but resulted in an overall cost of the RP corresponding to 1/3 of the cost of all TF coils.

Mechanical structures

Another specific aspect of the magnet system for fusion reactors is the need for mechanical structures to sustain the enormous forces acting on the coils. For example, for ITER the centering force per TF coil is 403 MN and the vertical force on one half of a TF coil is 202 MN. The maximum vertical force per coil is 327 MN and 160 MN for the CS and PF magnets, respectively (Mitchell et al., 2012).

For supporting the out-of-plane forces, in the inboard region the straight legs are wedged all along their side walls and the curved parts are linked by six pre-compression rings. In order to counteract the twisting moment of the TF coils due to the out-of-plane forces, the outer legs have been connected by the outer intercoil structures (OIS), which form toroidal shear belts around the magnets. The overall force balance in the TF set is maintained by the TF cases, including the central cylinder formed by the wedging, the inner pre-compression rings and the OIS.

The CS assembly includes the stack of six modules and a preload structure that compresses the CS magnet vertically during the assembly and the cool-down of the machine. The preload structure is made by a set of tie-plates located at the inner and outer diameters of the CS stack. The CS conductor has a very thick square jacket which is self-supporting against the radial and vertical magnetic loads.

Sliding supports allowing radial displacements are attached to the TF coil cases to support the PF coils. The structural support of each PF magnet is guaranteed by the thick square jacket of the PF conductor.

The future of magnet technology

The development of nuclear fusion power plants for supplying energy to the grid requires a consistent increase of the plasma volume or of the value of the magnetic field on the plasma compared to ITER, which is currently the largest reactor under construction. New challenges are expected for superconducting magnets in the design of the DEMOnstration fusion power plants. In the following sections the strategies adopted by the European DEMO are presented (Corato et al., 2018; Sedlak et al., 2020).

Improving performances of LTS magnets

The European DEMO design (Federici et al., 2019), whose major radius is about 9 m, is conceived to provide a plasma burn with a duration of 2 h. Scaling-up the ITER magnet design to DEMO is not impossible, but two relevant aspects must be improved. Firstly, the degradation of the performance of the conductor under electromagnetic cycles is not acceptable in a power plant that is expected to efficiently operate for tens of years. Secondly, the cost of magnet manufacturing must be reduced as much as possible to make a fusion power plant an economically viable source of energy.

In the European DEMO design the issue of degradation was successfully addressed using rectangular samples with a low void fraction and an increased stiffness of the cable. A first set of conductors has been realized using the R&W technology for Nb₃Sn superconductor (Sedlak et al., 2019), while a second type of superconductor has been manufactured with the W&R approach (Muzzi et al., 2017). For both types no degradation was observed after 1000 electromagnetic cycles and various thermal cycles.

The R&W technology presents an additional feature that might also reduce the cost of TF magnets compared to the ITER experience. Since the reaction HT is performed before the jacket is applied, the thermal strain applied to the cable during the cool-down is lower and this reduces the effective compressive strain acting on the superconductor. Since the performance of Nb₃Sn improves with lower strain (Muzzi et al., 2012), the net consequence is a reduction in the number of the required SC strands, compared to that of a W&R conductor carrying the same current.

Another strategy for optimizing the costs is to wind the conductor in (radially distributed) layers instead of (poloidal cross-section) pancakes. In fact, this approach allows grading of both SC and SS cross-sections in the different layers, increasing the amount of SC material and decreasing the amount of SS on the inner layers (i.e. facing the plasma), with the opposite trend on the outer layers.

HTS superconductors

The debate on the possibility of building a fusion power plant with HTS coils is very active (Whyte et al., 2016; Bruzzone et al., 2018) but the technology for large HTS magnets is not yet mature and requires an engineering demonstration, that includes the development of the following elements: high current HTS conductors, magnet protection devices and methods specific to HTS magnets, advanced radiation-tolerant insulating materials and coil fabrication technology.

In addition, to achieve demountable TF coils in a compact tokamak, such as ARC (Sorbom et al., 2014), the first objective is the development of the engineering design of WP joints for demountable coils. The key points to be solved in the design are the remote handling operations, the demounting activity, and the subsequent restoration of the cable connection with continuous insulation and structural support. All steps require quality and assurance procedures and experimental validation.

At present, an additional objection to the use of HTS is the high cost, one order of magnitude higher than that of LTS, which makes large HTS TF coils extremely expensive. However, in the European DEMO design a hybrid solution (HTS-Nb₃Sn-NbTi) based on layer winding has been proposed for the CS coil (Wesche et al., 2019). Compared to an LTS CS coil with the same outer radius, the hybrid configuration is more complex from the manufacturing point of view, but provides a more cost-effective design and a slightly higher magnetic flux.

It is worth noting that in high-field applications even HTS conductors need to operate at low temperatures, below 25 K, because the critical current density at high field dramatically drops above 25 K.

Plasma facing components

Plasma power exhaust and divertor protection

The description of the divertor operating concept and its underlying physics is discussed elsewhere (Reiter, 2020).

One of the crucial points in the dimensioning of a power producing fusion plant remains the size of the device and the amount of power that can be reliably produced and controlled within it. This heavily depends, among other things, on the heat load that can be tolerated by the divertor under normal and off-normal operation (Federici et al., 2019).

A Demonstration Power reactor to follow ITER must typically exhaust ~500 MW (~150 MW in ITER) of heating power (fusion alpha particle power and auxiliary heating power). If 40% of the exhaust power is radiated inside the magnetic separatrix, 300 MW will flow into the SOL. In order to achieve an acceptable heat load on the divertor targets, the latter are inclined at a shallow angle with respect to the magnetic field lines and located in a region near the separatrix X-point (magnetic null point) with significant magnetic flux expansion. In this way, the wetted area of the divertor targets in DEMO can be increased up to 1–2 m². Thus, if all the heat entering the SOL ultimately arrived at the divertor target (attached divertor regime), the power load would be above the capability of the highest performance state-of-the-art high-heat-flux technologies for steady state power load based, for example, on water-cooled copper alloys. To further reduce the heat load, part of the power flowing into the SOL has to be radiated in the divertor, leading to the so-called partially detached regime. This requires plasma temperatures in the proximity of the divertor target below 10 eV (Reiter, 2020).

Low temperature, detached divertor conditions also reduce the erosion of the divertor armor. The main erosion mechanism in the divertor is physical sputtering by plasma and impurity ions. These impinging particles transfer energy to the atoms of the armor materials. If the transferred energy is large enough, the target atoms can overcome the surface binding energy and leave the surface. The plasma temperature in front of the target defines the energy of the impinging particles by their Maxwell distribution and by the additional acceleration that the charged particles experience in the so-called plasma sheath in front of the surface. For plasma temperatures below 5 eV, physical sputtering approaches zero for tungsten as an armor material.

Another important function of the divertor is particle control, i.e. to provide adequate pumping capability to exhaust the neutralized gas, most notably the He ash, as well as to retain eroded impurities such that they will not enter the main plasma, which reduces fusion performance and can lead to plasma instabilities.

Siccinio et al. (2019) discusses the criteria to be employed in the preliminary phases of a tokamak fusion reactor dimensioning to ensure the integrity of the divertor for sufficiently long operating times, without, at the same time, compromising the stability of the

core plasma or the fusion power generation. It is shown that two high-level requirements must be fulfilled: (1) the concentration of seeded impurities in the SOL has to be lower than some critical value in order not to compromise the fusion plasma performance or stability; and (2) the design of the divertor target must be able to withstand accidental re-attachment of the plasma for a sufficiently long time to recover detachment or to ensure a reliable, controlled termination of the plasma discharge. The main conclusion of Kemp et al. (2018) is that, for a given fusion power level, the simultaneous fulfillment of both requirements limits the viable device size in terms of both major radius, R , and toroidal magnetic field, B .

Several solutions for the heat exhaust in DEMO are currently being explored in Europe 2020 (Turnyanskiy et al., 2015):

1. Baseline divertor solution—a combination of radiative cooling and detachment;
2. Innovative magnetic divertor configurations to achieve higher flux expansion thereby spreading the heat over a larger area, or to achieve longer divertor connection lengths and larger divertor radiated power;
3. Alternative solutions (e.g. liquid metals) that could exhaust higher heat loads.

However, the physics basis and the technology readiness level of solutions (2) and (3) remain low and it is to be expected that their relevance in terms of design constraints arising from DEMO integration and operation issues will require deeper scrutiny, if they are ultimately proved to be effective. A review of liquid metals as an alternative solution for the power exhaust of future fusion devices is provided by Coenen et al. (2014). The most attractive candidates under investigation are Sn and Li, and an R&D program is in place in Europe to investigate the power handling of realistic engineering solutions such as the capillary porous system (CPS). Critical issues that need to be resolved include, resilience to transients, design integration, vaporization/redeposition and tritium retention.

Although subjected to lower power and particle loads than the divertor targets, the first wall protecting the breeding blanket will also receive power from radiation and particles, and will undergo erosion. Robust engineering solutions are required for the components that directly surround the plasma to ensure that they can withstand the thermal and mechanical loads during normal and off-normal operation and that they contribute to protection of the outer components, especially the vacuum vessel and the magnets, from the effects of neutrons.

Considerations here are limited to the portion of the PFC surface that protects the main chamber (the so-called first-wall), which, for both JET and ITER, is made of beryllium. The strategy and the criteria adopted to design the PFCs of DEMO and ITER are substantially different. The problems associated with the design of the first-wall at JET and ITER are described by Federici et al. (2016). One of the main differences between ITER and DEMO is that for the latter to achieve efficient breeding (and therefore tritium self-sufficiency), the first-wall must be relatively thin (several mm) to avoid adversely depleting the neutron flux entering the breeding regions. In addition, conversion of this energy at adequate thermodynamic efficiencies requires that the coolants be at high temperature and pressure. This has a strong influence on reactor engineering. The ITER design uses a relatively thick Be-clad PFC actively cooled with water at low temperature.

The power handling capability of first wall in DEMO (i.e. the non-breeding part of the breeding blanket) is rather limited (~ 1 – 1.5 MW/m² for a water cooled concept and < 1 MW/m² for helium cooling) due to the requirement to use radiation-hard materials such as EUROFER steel for the structures and the cooling pipes of the breeding blanket, and high-temperature, high-pressure coolant for efficient energy conversion. Operation within these heat-flux limits is deemed to be achievable in nominal conditions in the present DEMO blanket designs, but the occurrence of plasma transients that may severely damage the first wall or even lead to a breach of the cooling pipes and a consequent loss of coolant remains a significant issue. Preliminary results of the R&D launched to address this problem are described by Maviglia et al. (2018). Tungsten foams are being investigated for use as armor for the protection limiters in the EU DEMO design (see De Luca et al., 2019). These limiters, in contrast to the plasma start-up limiters, will see very low heat loads during normal operation, but very high off-normal heat transient heat loads, and the benefit of a low thermal conductivity armor is the prevention of damage to the underlying cooling structures.

Design/engineering challenges for reactor application

Thermal loads

There are two major limitations to peak plasma heat exhaust.

- The continuous flow of power to the divertor plates and nearby surfaces that, for state-of-the-art technology with water cooling in a tokamak environment, is limited to 20 MW/m² peak heat-flux.
- The transient peak heat-flux that can be tolerated for a short time (< 1 ms) before substantial ablation and melting of the surface occurs; such common large transient events are Edge Localized Mode (ELMs) and disruptions (Lao, 2021). The material limit imposed by these events is of the order of ~ 40 MJ/m² s^{1/2} (Federici et al., 2003).

Accommodation of such high heat loads is very challenging and gives rise to several issues affecting the performance and lifetime of the PFCs, and influencing the choice of materials and design configurations. These issues are related to the armor and joint behavior as well as to the heat removal capability of the coolant. One of the key design drivers that has led to the selection of water as coolant for the divertor in the EU DEMO has been the much lower heat removal capability of helium-cooled components compared to water-cooling (typically 5–10 MW/m² vis-à-vis 10–20 MW/m² for water) (You, 2015a). Even more importantly, the ability of water-cooled components to absorb much larger transient heat fluxes (e.g. transition from detached to attached plasma lasting several seconds) easily exceeds the heat removal capability of helium-cooled targets, which cannot tolerate such excursions.

Nuclear loads

Neutron irradiation produces significant volumetric thermal power by gamma ray generation and causes serious material damage (crystal defects, transmutation). For example, in the EU DEMO, roughly 130 MW of fusion power is transferred to the divertor in form of nuclear heating in solid structures and in coolant. The maximum nuclear heating power density in the steel structure of the cassette body reaches roughly 5 W/cm^3 , with 6 W/cm^3 in the shielding liner heat sink (You et al., 2017).

In most metals, crystal defects (vacancies, interstitials, dislocation loops) cause hardening and embrittlement of the material when the irradiation temperature is not high enough to activate thermal recovery processes. A measure of material damage due to crystal defects is the average number of lattice displacement per atom (dpa). In the case of the DEMO divertor, the target armor (tungsten) and heat sink (copper) is predicted to experience 2 dpa and 7 dpa per full power year (fpy), respectively. The steel structure of the cassette body experiences damage of approximately 2 dpa per fpy (You et al., 2017).

Helium bubbles produced by nuclear transmutation are potentially the most critical cause of embrittlement. In a DEMO divertor target, a maximum helium production rate of up to 2 appm and 60 appm is foreseen for the target armor (tungsten) and heat sink (copper), respectively.

Mechanical loads

Under the thermal loads, a temperature gradient develops between heat sources and heat sinks (cooling circuit). In a divertor target, a steep temperature gradient builds up during stationary operation ($\sim 80^\circ\text{C/mm}$) and a slow transients ($\sim 200^\circ\text{C/mm}$). There will also be a temperature gradient along the longitudinal axis of a target element due to the non-uniform heat flux footprint. Such strong temperature gradients produce thermal stresses due to restraint. Additionally, significant thermal stresses (several 100 MPa) can be produced by a thermal strain mismatch between dissimilar joined materials (armor and heat sink) (Li et al., 2014; Li and You, 2016). The thermal stresses may cause material damage of different types leading to structural failure. Embrittled materials, in particular, are highly vulnerable to cracking and tend to exhibit a reduced strain resilience.

Design concepts

A vigorous R&D program on PFCs engineering is underway in Europe, as part of the DEMO Development Program (Federici et al., 2014) benefitting from lessons learned from ITER (see, for example Merola et al., 2010). This includes: (i) the design of the divertor cassette body, considering a number of variant layouts; and (ii) the development of several candidate divertor target concepts, including fabrication trials and high-heat flux tests (You et al., 2018). The crucial design requirements for the target are to ensure sufficient margins for power handling, including slow thermal transient events, and to accommodate the relatively high neutron irradiation dose expected for a DEMO divertor. The PFCs will operate in a harsh loading environment characterized by extremely severe and multiply combined loads. Cyclic loading due to pulsed operation causes material fatigue. Moreover, the DEMO divertor is required to fulfill further key functions, namely, nuclear shielding of adjacent vacuum vessel and superconducting magnets, and guiding gas flow for particle exhaust.

Divertor cassette system

In the case of a tokamak-type fusion device, the divertor consists of many discrete cassettes arrayed along the toroidal orientation. The European DEMO will have 48 divertor cassettes (ITER has 54 cassettes). Each cassette consists of two vertical targets (to block and baffle SOL particles on the outboard and inboard side), cassette body (to hold targets and to route gas flow), shielding liner or reflector plates (to protect the underlying structure) and a cooling circuit pipework (to feed coolant) (Marzullo et al., 2019). Fig. 3 shows a typical cassette system of the European DEMO divertor. The big duct located in the cassette body (left figure) is an opening for fostering gas flow toward a pumping port. This pumping duct is covered by a shielding liner (with a vertical gap) to protect the underlying vacuum vessel from neutron streaming.

Individual cassettes are deployed by remote handling operations via the lower ports of the vacuum vessel and distributed toroidally. During fusion operation, a strong radial inward magnetic force is generated in the cassette body (ferromagnetic steel) and exploited for fixing the cassette, which is attached to the inboard vessel.

The structural material of the cassette body, shielding liner and reflector plates is reduced activation EUROFER97 steel. It is ferritic-martensitic 9Cr steel where W and Ta are used as carbide-forming alloying elements. The upper service temperature limit is about 550°C , above which tensile strength begins to drop rapidly. The ‘desired’ lower service temperature limit is around 300°C , below which the steel undergoes a transition to non-ductile state after neutron irradiation (Tavassoli et al., 2004). The question whether a lower operation temperature, below 300°C , would be applicable for EUROFER97 depends on stress intensity and the applied structural design criteria (Mazzone et al., 2017).

A critical design element in divertor engineering is the target design. The baseline design of the DEMO divertor target mostly inherited the preceding design of the ITER divertor target, which is a so-called tungsten mono-block type (You et al., 2018) (see Fig. 4). The monoblock type design was firstly developed for the carbon fiber composite plasma facing material of the NET and ITER reactor designs (Toschi et al., 1988; Janeschitz et al., 1995) and it was later adapted to beryllium and tungsten armors. In this design, the armor surrounds the heat sink, yielding a particularly robust design, in particular for a high number of high heat flux cycles (Cardella et al., 1991, 1993).

The structural part of the target is the embedded cooling pipe (heat sink). Precipitation-hardened copper alloy (CuCrZr) is the baseline structural material, while tungsten wire-reinforced copper composite is considered as a back-up option (You et al., 2018). The ideal service temperature range proposed for irradiated CuCrZr ranges roughly from 250°C to 300°C with some margins (You, 2015b). The lower limit is determined by thermal recovery of ductility and the upper limit by the onset of thermal

Fig. 3 (A) Cassette system of the European DEMO divertor; (B) Full scale divertor cassette body manufactured for ITER. Source: ITER IO.

Fig. 4 A small mock-up showing the baseline design of the DEMO divertor target.

softening and irradiation-assisted creep. In recent design studies of target PFCs, the operation temperature range of CuCrZr pipe had to be extended (130 °C–430 °C) far beyond the ideal service limits (You et al., 2018). Dedicated design rules should be applied to cover the non-ductile design regime. Using a copper-base material for the target heat sink is deemed indispensable, as other relevant structural materials (e.g. steel) have a thermal conductivity that is too low to be used for high heat flux (HHF) applications.

Tungsten is used as plasma-facing armor (blocks) because tungsten possesses several unique, outstanding properties such as the highest melting point (3422 °C), very low sputtering yield, extremely low hydrogen solubility, relatively high thermal conductivity and high-temperature strength, and high thermal shock resistance, etc. A major drawback is its brittle nature at lower temperatures and strong embrittlement by irradiation. Under normal operation (10 MW/m²), tungsten armor reaches a maximum temperature of roughly 1100 °C at the surface.

Divertor cooling scheme

For the sake of longevity of the targets, early failure of the structural material (pipe) due to premature damage by coolant dry-out (or film boiling) should be avoided. To this end, a valid cooling condition needs to be defined in such a way that, at the region of the plasma strike point, the maximum wall heat flux of the cooling pipe does not reach the critical heat flux (CHF). There should be a sufficient margin (40%) to guarantee that either single-phase flow or subcooled nucleate boiling is maintained even during slow (~10 s) thermal power transient events where the heat load increases up to 20 MW/m² and the armor temperature reaches up to 2200 °C.

A similar rule is applied to the cassette body and the shielding liner. Considering the significantly higher nuclear loads and irradiation damage dose expected in DEMO than in ITER, two separate cooling circuits, each with a different thermo-hydraulic condition, are employed, as illustrated in Fig. 5, where the inlet water coolant temperature (with predicted temperature rise) and inlet pressure for each circuit is indicated.

HHF technologies

State-of-the-art technologies for divertor targets

In addition to the ITER-like target technology currently favored for the design of the DEMO divertor in Europe, (albeit with a reduced dimension), advanced technologies have been developed to improve structural reliability and material performance under

Fig. 5 Cooling circuits of DEMO divertor (left: cassette body, right: targets) and inlet coolant conditions.

combined HHF and irradiation loads. **Fig. 6** shows four selected examples of novel alternative options (together with the current baseline), where the essential features of design or material are highlighted. The first four cases refer to a mono-block type structure while the last one is a flat-tile type. Fabrication technologies are now quite mature for all cases and have demonstrated a good quality of production, as confirmed by non-destructive inspection (Visca et al., 2018).

HHF tests

All monoblock-type HHF technologies have been verified in an extensive HHF testing campaign using small-scale mock-ups at a neutral beam (hydrogen) test facility, exhibiting an excellent performance at 20 MW/m² (500–1000 pulses, 130 °C coolant), 25 MW/m² (100 pulses, 20 °C coolant), up to 32 MW/m² (5 pulses, 20 °C coolant) without any discernible major failure or damage (Greuner et al., 2019, 2020; Dose et al., 2019).

Fig. 7 shows in-situ infrared pyrometer thermographic images displaying the surface temperature of four different variants of tungsten monoblock-type target mock-up (shown in **Fig. 6**) in the course of HHF tests conducted at 20 MW/m² with hot coolant (130 °C). A distinct increase of surface temperature or occurrence of a hot spot may reveal a site of impaired heat conduction indicating material failure (mostly at a joining interface). The images exhibit no significant evolution of temperature for all target designs, demonstrating a reliable HHF performance at the targeted (i.e. specified for design) HHF load (note that the minor changes in color shading is attributed to the changing surface emissivity due to surface layer modification.). **Fig. 7** shows the photographs of two ITER-like target mock-ups, each with a different tungsten material, after an overload screening test (5 cycles at 32 MW/m²) followed by an HHF fatigue test (25 MW/m², 20 °C coolant). All armor surfaces were intact, exhibiting neither discernible cracks nor severe damage.

Vacuum vessel

Functions and configuration

In a tokamak, the vacuum vessel (VV) is a D-shaped toroidal pressure-retaining vessel with ports allowing access to the plasma. It is enclosed by the toroidal field (TF) and poloidal field (PF) coils, which form a cage-like structure whose interspaces are used to integrate the VV ports.

Vacuum and confinement: The VV maintains the ultra-high vacuum ($< 10^{-5}$ Pa) required for plasma operation. It is made of stainless steel with surfaces finished with stringent cleanliness requirements. Gases and impurities adsorbed on the VV inner surfaces after venting, during in-vessel maintenance, or after a vacuum leak, need to be desorbed to achieve the required quality and purity of the vacuum. Hence the VV is heated before pump-down to a temperature of 150–200 °C (Härtl et al., 2019). In devices subject to nuclear regulation, radioactive dust and tritium are confined within the primary vacuum of the VV and the structure must therefore be designed according to nuclear pressure vessel codes when pressurized water is used as coolant (Choi et al., 2014). These require a component reliability so high that failure is practically excluded and hence rigorous qualification, as well as in-service inspection, is required, as discussed below.

Neutron shielding: Fusion devices with copper coils typically do not require the VV to reduce the neutron flux. ASDEX Upgrade has a single-walled VV (Steibl et al., 2003). In JET the interspace of the double-walled VV is not filled with water, a neutron moderator, but is used as a secondary vacuum (Duesing, 1987). In fusion devices with superconducting magnets, however, the VV must contribute to the shielding of neutrons to limit the neutron heating of the magnets operated at cryogenic temperatures. To reduce the distance between the plasma and the TF conductor, and hence maximize the high field region accessible to the plasma, the space occupied by the VV (and dedicated to reducing the neutron flux on the inboard side) must be minimized (Bachmann et al., 2016). In devices with high lifetime neutron fluence, such as ITER (0.3 MWyr/m² Juárez et al., 2018) or DEMO (approx. 6 MWyr/m² Fed-erici et al., 2019), the neutron flux must be further reduced, in particular on the outboard side, to avoid excessive activation of the components inside the cryostat and hence to allow the access of personnel in exceptional situations requiring unplanned maintenance. For the VV to shield neutrons efficiently a double-wall steel structure, filled with liquid cooling water acting as neutron moderator, has proven to be most suitable (**Fig. 8**). Additional plates of borated steel are stacked in the interspace to reach a favorable mixture of steel and water of about 60/40% by volume (Loughlin et al., 2011). The significant weight of the ITER VV associated

Fig. 6 Selected examples of novel alternative target technology options.

Fig. 7 (A) In situ infrared pyrometer thermographic images displaying the surface temperature of four different variants of tungsten monoblock-type target mock-up in the course of HHF fatigue tests at 20 MW/m^2 with hot coolant (130°C). (B) Photographs of two ITER-like target mock-ups, each with a different tungsten material (lower: AT&M, upper: ALMT), after an overload screening test at 32 MW/m^2 followed by an HHF fatigue test at 25 MW/m^2 (You et al., 2020).

with this design approach is shown in Table 1. Note that in KSTAR (a non-nuclear device) the cooling water is also borated to further enhance the neutron absorption (Kim et al., 2008).

Mechanical integration: In order to avoid high thermal stresses due to differential thermal expansion, different high stress interactions and thermal conduction from the VV to the cryogenic coils (Farfaletti-Casali et al., 1984), the VV is supported independently of the magnets. Moreover, in nuclear devices such as ITER, the safety-classified VV cannot be supported by the non-safety-classified magnet system.

Precision: The VV supports the in-vessel components (IVCs) and hence the plasma-facing components, mainly the blanket first wall (FW) and the divertor targets. The VV has stringent manufacturing and assembly requirements. Leading edges of the PFCs

Fig. 8 View of four sectors of the assembled ITER VV with upper, equatorial and lower ports and IVC support structures (pink) on the inner shell. Support structures below the lower ports and port plugs not shown. The splice plates used to assemble the sectors and some of the ports are highlighted in dark gray. From ITER organisation.

Table 1 Major dimensions and weight of the ITER VV.

Major dimensions		Weight (tons)	
Outer diameter (m)	29.0	Main vessel	1611
Height (m)	11.3	Shielding	1733
Double wall thickness (m)	0.34–0.75	Ports	1781
Interior surface (m ²)	850	Supports	111
Interior volume (m ³)	1600	Total	5236

would be subject to excessive heat loads due to charged particles escaping from the plasma confinement (Maviglia et al., 2017). It is therefore necessary to align the PFCs to the toroidal field with a precision that, for components of this size, is uncommonly tight: in the EAST tokamak the alignment of the PFCs to the magnetic axis is less than ± 0.5 mm (Wenge et al., 2005). The ITER FW has a prescribed alignment tolerance of ± 5 –10 mm (Wilson et al., 2015) and the ITER divertor targets of ± 2 mm (Escourbiac et al., 2012). Given the foreseen integration of protection limiters the alignment requirement of the DEMO BB FW might be somewhat relaxed but still high, currently estimated as ± 5 –10 mm (Vizvary et al., 2019). The customization of the individual IVC support structures can compensate misalignments of the VV inner surface to some degree (Wilson et al., 2015). However, for the successful installation and alignment of the PFCs, small VV tolerances are required, e.g. ± 3 mm in JET (Duesing, 1987), ± 5 mm in JT60SA (Shirai et al., 2017), and ± 10 mm in ITER (based on large-scale fabrication studies Nakahira et al., 2008).

Electromagnetic integration: In tokamaks, to enable plasma operation, the currents in the PF and CS coils are varied for three different purposes: (i) to provide toroidal magnetic flux to break down the hydrogen gas into a plasma and initiate the discharge, (ii) to drive the plasma toroidal current, and (iii) to actively control the plasma shape and the plasma radial and vertical positions. The VV is subject to the resultant magnetic field variations as it is a toroidally continuous structure. To reduce its EM shielding effect during plasma breakdown, several existing tokamaks integrate bellows or electrical breaks between the VV sectors, increasing the toroidal resistivity, e.g. JET (Crisanti et al., 2003), ASDEX Upgrade (Steibl et al., 2003) or JFT-2M (Mori et al., 1988). Shunts can prevent arcing at the bellows and at electrical breaks between the VV sectors (Mori et al., 1988). On the other hand, in the case of plasma vertical motion, the toroidal electrical conductivity of the VV causes currents to be induced that counteract the plasma movement, providing passive vertical stability (Albanese et al., 2004). Due to their flexibility, bellows between VV sectors prevent the VV acting as a ring structure that would be well suited to bear vertical and out-of-plane loads. Operational experience with tokamaks having vertically elongated plasmas showed that the VV's role in the passive stabilization of vertical plasma motion was an important factor in limiting the loss of vertical position control. In addition, vertical displacement events (VDEs) associated with such loss of control produced significant forces on the VV and in-vessel structures. Consequently, the occurrence of VDEs required the JET VV to be reinforced (Buzio, 1998). With the increase of the plasma currents, e.g. toward JT-60U and ITER, the VV design approach incorporating bellows or electrical breaks was abandoned. In NET, it had been attempted to maintain the structural toroidal continuity while at the same time integrating bellows between sectors (Anon, 1993). The concept was later abandoned in ITER (Ioki et al., 1998). The fact that the use of bellows was unprecedented in nuclear containment vessels and the expected difficulties in obtaining a nuclear license was also an important consideration. Both shells of the ITER VV sectors will be fully welded at the sector field joints using splice plates (Choi et al., 2014) and the same principle is envisaged for DEMO. Due to progress in

operational techniques for establishing plasma breakdown, the use of a toroidally continuous VV is no longer considered a major issue (Lloyd et al., 1996; Ambrosino et al., 2015; de Vries and Gribov, 2019).

Material and sustainability

Vacuum vessels in existing devices are fabricated from a range of austenitic steels for their good mechanical properties and good weldability, e.g. 316 LN (EU 1.44xx steels) in KSTAR (Kim et al., 2008), JT60SA (Shirai et al., 2017), Wendelstein 7-X (Cardella et al., 2007) and ITER (Ioki et al., 2010). Nicrofer 7216 LC, which is similar to Inconel 600, was used in JET (Duesing, 1987), Inconel 625 in JT-60U and AISI 321 in T-15M (Mironiv et al., 2004). In DEMO the VV will be subject to a significant level of neutron irradiation, which introduces two additional aspects to be considered in the material selection, namely the degradation of the material properties and the material activation. These considerations relate mainly to the inner shell since the neutron flux decreases through the VV thickness, by about one order of magnitude per 10 cm (Flammini et al., 2016). The irradiation resistance of austenitic steels is judged (Stork et al., 2014) as sufficient even for fusion power plants with 30 years of operation time. The degradation of the fracture toughness of 316 LN austenitic steel is defined in the nuclear code RCC-MR as negligible up to a damage level of 2.75 dpa (Bachmann et al., 2018), which is somewhat higher than is predicted to occur in DEMO (Fischer et al., 2016). A similar radiation resistance can be expected for the higher strength austenitic steel XM-19 (used for the ITER inner divertor target body) (Pokrovsky and Fabritsiev, 2011). One drawback is the high nickel content of austenitic steels and its long-life isotopes, which make the VV a major contributor to the intermediate-level waste produced by DEMO (Gilbert et al., 2019) and hence impact on the sustainability of fusion energy, see Fig. 9.

To date, the search for a non-nickel steel for the DEMO VV has not been successful: ferritic steels, as used in fission reactor pressure vessels and experiencing a dose of approximately 0.1 dpa, seem—based on (IAEA, 2009)—to have an radiation resistance of no more than 0.1–1 dpa. On the other hand, the radiation resistance of ferritic-martensitic steels is sufficient (> 5 dpa Brachet et al., 2001) and the reduced-activation steel EUROFER (Tavassoli et al., 2004) would be a candidate material for the VV from the point of view of neutron irradiation. The material is, however, ferromagnetic and shows poor machining, poor forming and poor welding characteristics. Welding EUROFER necessitates complying with small temperature ranges for preheating (100–150 °C), intermediate layer temperature (< 280 °C), soaking against hydrogen-induced cold cracking (250–300 °C), cooling down and post-weld heat treatment at 760–800 °C to recover the material's ductility. In particular, no technical concept has been found that would allow adequate control of the temperature of the sector field-joint welds during assembly, those on the inboard being accessible only from the plasma side due to the presence of the TF coils. Based on current fabrication capabilities, the use of EUROFER does not appear technologically feasible for a complex DEMO VV sector, which will be larger than that in ITER and require numerous sequential welds, see Fig. 9. Therefore, it is foreseen to use austenitic stainless steel for the structural parts of the DEMO VV, as in ITER.

To reduce the irradiated waste associated with the DEMO VV, the following principles are envisaged: (i) In order to reduce the amount of steel used in the most exposed part, i.e. the inner shell, high-strength steels might be considered. XM-19 might be a suitable candidate but further qualification is needed. (ii) Since no welding is required for the in-wall shielding plates, non-nickel steel is foreseen for those below the inner shell and still exposed to significant neutron flux. The European Power Plant Conceptual

Fig. 9 Vertical cross-section through the DEMO VV and in-vessel components, showing the predicted time to acceptance as low-level waste based on the UK waste classification, (the red line represents the VV inner shell). In-wall shielding plates are assumed here to be made of non-nickel steel.

studies (Maisonnier et al., 2005) foresaw a semi-permanent EUROFER shield covering the VV. This additional in-vessel component could reduce the activation of the VV sufficiently to allow its classification entirely as low-level waste.

Fabrication

The VV is typically fabricated as individual sectors that are welded together in the tokamak pit after the installation of the TF coils. The VV ports are manufactured separately and later joined to the sectors (Utin et al., 2013). In ITER the manufacturing processes include cutting, machining and forming of parts of the shells and ribs, welding, installation of in-wall shielding plates, weld inspection and leak testing (Choi et al., 2014; Ioki et al., 2010). To reduce weld shrinkage, welding technologies are chosen with minimal heat input such as narrow gap TIG and electron beam (Dans et al., 2014). In the design of the VV, provisions need to be taken to allow for non-destructive inspection of the welds, e.g. by radiography or ultrasound testing (Martinez-Ona et al., 2013). The challenging fabrication of the ITER VV sectors and ports is already underway, see Fig. 10.

Operation

Cooling

Tokamaks with short pulses and low neutron generation did not require an active cooling system for the VV. Temperature control systems were installed mainly to allow heating of the VV for vacuum conditioning via baking. In stellarators (e.g. W7-X) and in tokamaks with high performance and long pulses (e.g. JT-60SA) the VV is provided with active cooling. In ITER and future devices with long pulses and high neutron production rates, a significant amount of heat is deposited in the VV, e.g. in DEMO about 65 MW (Bachmann et al., 2016). A cooling water system removes this heat during plasma operation and is also used to heat the VV for baking. Since the IVCs will be activated, but are not expected to be safety-classified in accident scenarios, the VV cooling system will be essential for removal of the decay heat from the reactor. In the event of a loss of off-site power, the natural circulation of the VV cooling water might be sufficient. In ITER, however, a relatively small safety pump (44 kW) will be used, powered by safety-classified emergency diesel generators.

Loading conditions

The VV of ITER and large future devices with design points similar to the European DEMO (Federici et al., 2019) must be designed to withstand a range of mechanical, thermal, electromagnetic and seismic loads, which, for ITER, are summarized in (Martinez et al., 2014). The external pressure of 1 bar as well as the accidental internal over-pressurization condition (up to 2 bar in ITER Martinez et al., 2014) are not design drivers for the vessel with the exception of some parts of the port structures and the port closure plates. Instead, the pressure required to prevent boiling of the coolant water during baking at $\sim 150\text{--}200^\circ\text{C}$ (Härtl et al., 2019) defines the number of ribs to be welded between the two shells. Due to the neutron shielding function, which requires large amounts of steel in the VV, and due to the blanket weight, in particular in devices with a full tritium-breeding blanket, the dead weight carried by the VV supports is very large (~ 8900 tons in ITER and $\sim 27,000$ tons in DEMO). Seismic loads are usually less severe than EM loads, even at the ITER site, which has a rather severe ground spectrum (Sannazzaro et al., 2009).

Plasma disruptions generate large electromagnetic forces on the VV, as well as on the IVCs (Noll et al., 1997; Hender et al., 2007). Possible consequences include significant pressure loads on the VV shells, vertical and sideways net forces, and challenging interface loads on the supports of the IVCs (Martinez et al., 2014).

Fig. 10 ITER VV sector during manufacturing at Hyundai Heavy Industry in South Korea (September 2019). Source: ITER IO.

In order to protect the TF superconductor from over-heating in the event of a quench, a TF coil fast discharge is initiated to rapidly reduce the coil current using a dump resistor. The consequent poloidal current that is induced in the vessel interacts with the magnetic field that is still present in the initial phase of the discharge. This generates a pressure load on the VV acting away from the plasma that is particularly strong on the inboard side. In devices larger than ITER, this load can become critical, since the induced current increases with the size of the TF coils and the stress level in the VV is proportional to the inboard radius of the VV, which is large in devices with long inductively-driven (i.e. by the central solenoid) plasma pulses (Kovari et al., 2016). A slower discharge of the TF coils might be necessary to mitigate this issue in future tokamaks, which would, however, require an increase of the copper fraction in the superconductor (see Section “Cable-in-conduit conductors”).

In-service inspection (ISI)

Design codes for fission reactor pressure vessels, e.g. ASME Section XI in the US and AFCEN RSE-M in France, require regular pressure and leak tests, as well as the regular inspection of all welds, at an interval of 4–10 years, or individual inspections following accidents upon request of the regulatory authority. In the same way, ISI is mandatory for fusion reactor VVs, which are defined as nuclear pressure equipment. Ultrasonic testing might be a candidate technique for weld inspection; due to the high residual gamma radiation, radiographic inspection is excluded. Both shells are fully covered by other tokamak components, which restricts the access to most VV welds: the outer shell by the thermal shield, the inner shell by the IVCs. In particular, on the inboard side the compactness of the tokamak radial build is essential for the plasma performance (Kovari et al., 2016) and the provision of space for inspection tools has a substantial cost impact. In DEMO and future fusion plants, however, regular survey of the inner shell might be possible when the IVCs reach the end of their irradiation lifetime (Federici et al., 2019) and are being replaced. The design of future fusion plants needs to incorporate access for ISI tools and must aim to reduce the number of welds in the VV, e.g. in ITER the VV inter-modular keys are machined from a forged piece (Ioki et al., 2013) and complex 3D formed parts are used for parts of the shells (Jones et al., 2007; Ioki et al., 2010). A potential solution is that some welds with poor accessibility might be exempted from ISI if they are designed with additional margins. In ITER, ISI of welds is emphasized for those welds in higher stress areas (Ioki et al., 2013).

Remote maintenance

Maintenance in fusion reactors

The reliability of in-vessel components is among the foremost considerations for the successful development and deployment of future fusion reactor systems.

The effects of thermal loads and of highly energetic neutrons on the plasma-facing components lead to a progressive degradation of their properties. This reduces the lifespan of plasma-facing components, so that they require regular replacement. Hence, fusion reactors have inherently high planned maintenance frequency requirements compared to other types of power plants.

Neutrons also lead to material transmutation, and hence the activation of the plasma-facing components. The activation levels for commercially relevant power plants will be such that human access will be precluded anywhere in the plant where activated components may be present. This is not simply limited to the confines of the bioshield: many of these components must be extracted from within the bioshield for maintenance and processing in other parts of the plant. The presence of activated erosion dust and tritium also implies that any systems, which enter the vacuum vessel, such as remote maintenance equipment, may also be contaminated.

Aside from radiation risks, fusion reactors also contain hazards from a wide range of sources, including hazardous substances (e.g. beryllium), cryogenics, high voltage, industrial machinery, etc. The combination of all these hazards means that human access must be severely restricted in many parts of the plant. Carrying out maintenance activities safely therefore requires the use of remote equipment.

The availability of a power plant is the fraction of time it is operational and producing useful power (and hence, profit) over its lifetime. It is a key driver for commercial viability, which means uptime must be maximized and maintenance durations minimized. When considering also the neutron-induced degradation and the limited safe access available, it follows that an efficient maintenance strategy, supported by robust remote maintenance technology, is mission-critical for the commercial viability of fusion power.

Maintenance strategy

Maintenance is not limited only to in-vessel components: almost all systems inside the plant will require some form of maintenance. This can include anything from statutory inspection of welds, replenishment of consumables, replacement due to wear or corrosion, calibration, repair of damaged parts, etc.

For a reactor to be able to meet all its operational, commercial and regulatory requirements over its entire lifetime, a very high level of integration is needed between component, reactor, and maintenance system designers. This can only be achieved if the maintenance strategy is incorporated from the outset in a Maintenance Management Plan (Tesini and Rolfe, 2009) and used to drive the design of the reactor and its subsystems (Raimondi, 1989a; Rolfe, 2007; Tesini and Palmer, 2008). An example of this is ITER's

maintenance classification scheme (David et al., 2009), which assists component designers in providing a first assessment of the maintenance requirements early in the design process, and in communicating these to the maintenance specialists.

Designers must consider that, during maintenance, components will be subjected to a wide range of non-operating conditions over several decades. For instance, at times they may be only partially assembled, moved to new locations, held in different positions, stored in hot/cold rooms, require aggressive decontamination, etc.

Contamination control and safety are driving considerations because maintenance activities often involve the relocation of components between different parts of the plant. This can increase the likelihood of contaminants such as radioactive dust being mobilized, so that activities must be carefully planned, and additional control measures deployed as needed.

Maintenance activities often need a variety of specialist tools and equipment, each with individual requirements. Two major considerations which affect the layout of the plant are space (requirements for transporting components, temporary storage, installing temporary contamination control barriers, access and operation of maintenance equipment, etc.) and provision of services (electricity, hydraulic power, cooling fluids, cleaning fluids, laser sources, etc.). Both are typically required close to where the maintenance activity is taking place. Retrofitting space and services into the design once the plant is built is costly and often unfeasible.

Remote maintenance technology

In locations where human access is prohibited, remote means are required to perform maintenance activities. Historically, these have involved using teleoperated robots, which are controlled by human operators from the safety of a control room.

The remote maintenance system of the Joint European Torus (JET) (Raimondi, 1989b) is the most developed and comprehensive of its type, having accumulated over 30,000 h in operation (Buckingham and Loving, 2016). It uses two snake-like booms to enter the vacuum vessel (Fig. 11, left). These move around the vessel controlled remotely by operators, carrying other subsystems and payloads such as the MASCOT telemanipulator (Fig. 11, right). The booms are reconfigurable to adapt to a wide range of missions. They measure 12.5 m at full extension and are capable of carrying 650 kg payloads. A similar deployment principle is used for the Articulated Inspection Arm, used in the EAST and WEST devices (Villedieu et al., 2016). Although limited to 10 kg payloads, it can operate under vacuum conditions.

Some complex tasks may require highly bespoke handling equipment, such as divertor cassette replacement in ITER. The reference design of the Divertor Remote Handling System (Fig. 12) consists of two movers (Esqué et al., 2014). The Cassette Multifunctional Mover transports the ~10 ton divertor cassettes radially to and from the vessel through the maintenance port. Several interfacing end-effectors also allow it to transport a range of other hardware and remote handling equipment. The Cassette Toroidal Mover locates the cassettes inside the vessel, moving them along toroidal rails. A variety of tools are used to cut and weld divertor cooling pipes, lock the cassettes in place, and collect contaminated dust from the work area. These tools are deployed with a dexterous, teleoperated manipulator arm, mounted on the movers.

Remote operations, maintenance equipment and reactor components must all be designed together, as all associated constraints must be considered in an integrated way to achieve a successful design satisfying the lifetime operational requirements. As a result, design verification and validation typically require physical mock-up testing, where operations, equipment and components can be shown to work together as intended in a representative setup (Rolfe, 2007; Tesini and Palmer, 2008). The JET In-Vessel Training Facility is a full-scale mock-up of the JET vessel that has been used extensively to support reliable operations inside the reactor, and to train JET operators to the necessary levels of competence (Cusack et al., 1997). The ITER Divertor Test Platform 2 facility

Fig. 12 Overview of ITER's divertor remote handling system (Esqué et al., 2014). From Esqué S, van Hille C, Ranz R. et al. (2014) Progress in the design, R&D and procurement preparation of the ITER Divertor Remote Handling System. *Fusion Engineering and Design* 89(9–10): 2373–2377.

provides a further example. This has allowed extensive testing to ensure that the design concept for the Divertor Remote Handling System is feasible (Saarinen et al., 2011), given that it must be able to operate in a highly constrained space and in the presence of gamma radiation.

The cost of remote equipment failure can be prohibitive, as the limited access makes rescue and recovery operations very complex and time-consuming. The more likely equipment failure modes, or those with particularly negative consequences, are eliminated from the system at the design stage. If a failure mode cannot be eliminated, the likelihood of it occurring can be reduced by providing a redundant system to prevent loss of function. Systems should fail in a known and controlled manner, such as lifting interfaces remaining closed in the case of a power failure to prevent payloads being dropped. Where possible, all remote maintenance equipment should allow recovery, which is defined as the ability of the system to extract failed subsystems from the restricted area using only its existing capabilities. In contrast, rescue is defined as the removal of failed equipment using external means, such as additional robots. All remote equipment must be rescuable.

In future reactors, the boundary of the restricted access area will expand as activation levels increase. In JET, the prohibited access area during maintenance is limited mostly to the vacuum vessel. Plasma-facing components are handled in the dedicated Beryllium Handling Facility, which is restricted to personnel wearing pressurized suits due to the toxicity hazards of beryllium particulates. However, radiation levels of ITER components will be much more significant (than in JET), so a dedicated hot cell with specialized remote equipment is required to process components leaving the reactor (Friconneau et al., 2017). In future systems it is expected that an entire Active Maintenance Facility will be required to process the highly activated components, with many large areas being out of bounds for human access (Thomas et al., 2014). This expanding boundary implies that the number of maintenance activities that must be performed remotely will increase dramatically.

The future of remote maintenance

Fusion reactors following ITER will face further challenges, related to the additional requirements as designs approach commercial deployment.

Higher fusion power will lead to increased activation and to higher radiation levels during maintenance, which will be sufficient to damage electronic systems that are not properly shielded. Deployment of robotic systems inside the vessel, while still possible for ITER, will be unfeasible for DEMO and future power plants unless adequate radiation-resistant technology is developed (Bachmann et al., 2018).

A key challenge for future fusion reactors is their larger size, which means very large components need to be handled with high precision. For instance, ITER requires a bespoke deployable rail system to handle the $1\text{ m} \times 1.4\text{ m} \times 0.5\text{ m}$, 4.5 t blanket modules (Raffray et al., 2014; Noguchi et al., 2018). The largest components in DEMO could be $\sim 10\text{ m}$ tall, have masses in the order of several tens of tonnes, and require a positioning accuracy in the order of $\pm 20\text{ mm}$ (Keep et al., 2017; Keech et al., 2019). The handling strategy for such large components is a fundamental driver for the architecture of the entire plant (Utoh et al., 2015; Wolff et al., 2017).

To reach commercially-relevant levels of plant availability, the speed of maintenance systems and the ability to perform tasks in parallel must improve significantly. Human-in-the-loop systems are inherently limited in these areas, and so it will be necessary to automate many maintenance activities, leveraging the productivity improvements already demonstrated in manufacturing industries worldwide. However, deployment of automated and autonomous systems with reduced human supervision in such harsh environments is a significant technology challenge, particularly considering the need for acceptance by regulators.

Given that many remote systems will need to be deployed, they will have to be highly reliable to minimize equipment failures during maintenance operations, which would otherwise reduce plant availability. This will require the adoption of more intelligent condition monitoring techniques which can give advanced warning of failures to better mitigate their consequences.

The connection of services (power, cooling & breeding fluids, etc.) is time consuming (Keogh et al., 2018). This problem is exacerbated by the higher temperatures that the components will experience, which increases the number and size of active cooling connections needed. Techniques are required which allow faster making and breaking of these connections, such as in-bore laser cutting and welding (Keogh et al., 2018).

Concluding remarks

Magnetic fusion is an attractive source of abundant and clean energy, but the endeavor to harness fusion power is technologically challenging. A limited number of fusion facilities have been built and successfully operated around the world during the last decades to investigate fundamental plasma physics issues that underpin the design of a new generation of power producing designs. Sustained progress over several decades has taken fusion close to the demonstration of the scientific feasibility of large-scale fusion energy production, with ITER expected to achieve operating conditions approaching those of a power reactor. ITER will also be a critical test of the reliable operation of a number of important engineering systems and core technologies.

Focus is now shifting toward the design and R&D of systems that, after ITER, will demonstrate the production of net electricity, the feasibility of operation with a closed tritium fuel cycle, and maintenance systems capable of achieving adequate plant availability. This is essential to overcome the remaining daunting technological hurdles to practical fusion energy.

In several key technologies further R&D will be essential to improve performance and reduce costs.

Superconducting Magnets—The main technological challenge for superconducting magnets is reducing the degradation of the performance of the conductor under electromagnetic and thermal cycles. This issue could prevent the optimal and reliable operation of magnetic fusion reactors over tens of years. Future research will be driven by the development and qualification of SC conductors to mitigate this risk.

The cost of magnets manufacturing must also be reduced where possible to make a fusion power plant an economically viable source of energy. Cost-effective solutions, such as the R&W approach to Nb₃Sn magnet manufacture and an efficient use of HTS coils, need to be pursued and validated with dedicated R&D. The effectiveness of the selected solutions should be demonstrated by long-length industrial production and, in the engineering phase, through the manufacturing and the testing of model coils.

Plasma facing components—R&D is required to substantiate the power handling performance of the high-heat-flux solutions under development, including the influence of neutron irradiation. The key elements in this regard would be: (1) full high-heat-flux qualification of a state of the art baseline PFC concept at relevant irradiation dose (e.g. as a post-irradiation test); and (2) development and qualification of novel neutron-resistant materials and joints for an enhanced lifetime. An early engagement of a dedicated irradiation testing campaign would be necessary to reduce the gap between the technological readiness and the design progress. Attention must be given to specific combinations of heat flux (i.e. temperature level) and irradiation fluence (i.e. damage level) at different areas of PFCs so that material requirements being pursued are in accordance with the envisaged design space. In parallel, dedicated structural design rules need to be developed on the basis of valid materials irradiation test data and failure criteria tailored for PFCs. Finally, adaptation to industrial manufacturing processes and incorporation of innovative fabrication technologies will remain future objectives.

Vacuum Vessel—The design and technology of the ITER VV are largely suitable for future fusion power plants. The stainless steels used in ITER and other existing machines are suitable for the higher neutron fluence expected in such devices. The fully welded double-wall design is an established concept and it is expected that the installation procedure of the ITER tokamak will validate the assembly of the sectors and ports structures. Construction in accordance with nuclear pressure vessel design codes, which require very high levels of qualification, is a significant cost driver. The ITER operational experience could result in the possible use of a more specific “Fusion Code” in future devices that might mitigate code requirements and reduce costs. To improve the sustainability of the VV some measures can be taken to reduce the amount of VV material that will remain activated over a long period. In future fusion devices, such as DEMO, that are larger than ITER, the VV inboard wall will be subject to higher EM forces and may require the use of a higher strength steel. To allow the in-vessel components to be installed with high alignment precision, the acceptance tolerances of the inner VV shape must be small and are usually at the limit of what can be achieved. Consequently, difficulty, risk and cost of the VV fabrication and assembly increase. The designers of future fusion power plants may succeed in including a greater customization range in the design of the support structures of the in-vessel components and hence relieve the requirements on the VV shape tolerances. Moreover, overall standardization and uniformity of the VV design and manufacturing methods should be emphasized in future fusion plants to reduce cost, to increase reliability and to mitigate tolerance issues. In addition, the implementation of plasma limiters can reduce the alignment requirements of the blanket first wall. The development of the VV of DEMO and other future devices will greatly benefit from the lessons learned and the solutions adopted in the nuclear licensing process of the ITER VV, e.g. regarding fabrication processes and their qualification and in the facilitation of in-service inspection, resulting in manufacturing cost reductions.

Remote Maintenance—As the radiation boundary expands inside fusion power plants, so too will the number of maintenance tasks that will have to be performed remotely. Combined with the increasing size and mass of reactor components and the need to achieve commercially-relevant plant availability, it follows that future remote maintenance systems will need to be faster,

more capable and more automated. To achieve this, future fusion plants will need to evolve highly integrated designs where the maintenance strategy is considered from the outset and built into the very architecture of the plant.

Acknowledgments

The authors wish to thank and acknowledge the following useful discussions: for the Vacuum Vessel Section with Antonino Cardella, Kimihiro Ioki, Yuri Utin (ITER IO), Chang-Ho Choi (ITER IO), Jean-Marc Martinez (ITER IO) and for the contributions regarding activation waste with Mark Gilbert (UKAEA) for the Vacuum Vessel Section; for the Plasma facing Components Section with the team of experts working in the WPDIV of the EUROfusion Consortium.

This work has been carried out within the framework of the EUROfusion Consortium and has received funding from the Euratom research and training programme 2014–2018 and 2019–2020 under grant agreement No 633053. Glossary

Bootstrap current A non-inductive and spontaneous plasma current which arises when plasma pressure gradient is high. When the bootstrap current accounts for the majority of the plasma current, it will improve the economic efficiency of fusion reactors. For economical fusion reactors, the ratio of bootstrap current to the total plasma current needs to be 75% or more.

Electron cyclotron resonance frequency (ECRF) Uses RF waves with frequencies in the range from several tens to hundred GHz and mainly heats plasma electrons. It is also used for current drive in both central and peripheral region of plasma.

ELM Edge Localized Modes (ELMs) is an intermittent and periodic heat and particle release phenomenon that occurs in the plasma edge of the improved confinement mode called H-mode. The ELMs are necessary to keep the H-mode plasma steady, but there is a concern that the large energy released intermittently will damage the divertor material, and research to control the ELMs to small amplitude has been vigorously carried out.

ELMy H-mode Improved confinement mode called H-mode having ELM. H-mode without ELM is called ELM-free H-mode.

Fusion gain factor Q Ratio of fusion output power to input external power. The condition with $Q = 1$ is called break-even plasma condition, the fusion reaction produces energy equal to the energy injected externally. $Q = \infty$ is called self-ignition condition, the fusion reaction can be sustained without further external heating input in the condition. ITER aims to achieve burning plasma with $Q=10$ or more.

Internal transport barrier (ITB) ITB is a phenomenon in which the thermal conductivity of the plasma is drastically reduced at a certain radius inside the plasma, resulting in a significant improvement of the confinement performance and the formation of a steep temperature gradient, which was first discovered in JT-60. Since then, similar phenomena have been reported in many

tokamaks and are common to many high-performance plasmas, and have been studied worldwide as a key phenomenon to improve plasma confinement.

Ion cyclotron range of frequency (ICRF) uses RF waves with frequencies typically in the range from 10 to 100 MHz and mainly heats plasma ion. This heating method is usually referred to as ion cyclotron radiofrequency (ICRF) heating.

Landau damping In a non-collisional plasma where collisions between particles are negligible, wave energy is attenuated by the energy exchange between waves and particles. Particles traveling at a speed approximately the same as the phase velocity of the wave can exchange energy by interacting with the electric field of the wave. It means that particles slower than the phase velocity of the wave are accelerated by the wave and particles faster than the phase velocity of the wave are decelerated by the wave.

Lower hybrid range of frequency (LHRF) The LH waves have been used for current drive (LHCD) in the peripheral region of plasma, with typical frequencies in the range of several GHz.

Negative magnetic shear (or Reversed magnetic shear) In the negative magnetic shear, the magnetic shear becomes negative in the plasma confinement magnetic field configuration of the torus system. The negative magnetic shear configuration is considered to be a suitable configuration for steady-state tokamak reactors because it is compatible with a high bootstrap current fraction.

Neoclassical tearing mode (NTM) instabilities A type of resistive instability found in tokamak plasma, and likely to occur in high beta plasma with a positive magnetic shear and a large plasma pressure gradient. NTM forms magnetic islands on its resonant rational surface around the plasma, causing a plasma pressure drop. In order to stabilize NTMs, an external current injected into the inside of the magnetic island is applied, for example, using electron cyclotron wave power, which can be injected effectively within the width of the magnetic island.

Plasma disruptions There are two kinds of plasma disruption caused by thermal decay and plasma current collapse. The former impacts the thermal load on plasma facing components and the latter generates an electromagnetic force on the vacuum vessel and an in-vessel component.

Introduction

This article provides an overview of key technologies required for plasma production, initiation, and the sustainment of fusion reactions by Fueling, Heating and Current Drive, Diagnostics and Plasma Control.

The fusion reaction is initiated once the plasma reaches a certain density and temperature. To increase the plasma density, the Fueling System is firstly required to supply D_2 gas of a certain amount into the vacuum vessel and subsequently to provide a mass flow (in the form of gas or solid cryogenic pellets) at a certain rate to raise and maintain the plasma density. In a reactor, this mass flow would consist of a mixture of D_2 and T_2 . Once the plasma is initiated, it is sustained utilizing a magnetic field generated by the coils surrounding the vacuum vessel. In some magnetic confinement systems, such as the tokamak, a magnetic field generated by an electric current flowing within the plasma is also utilized as part of the confinement magnetic fields. This plasma current is initially generated within the plasma by inductive action of some of the external coils, but in a reactor it would be preferable to drive the current continuously by non-inductive means, including a contribution provided by Heating and Current Drive Systems. A key role of the Heating and Current Drive Systems is to heat the plasma to a required temperature of the order of 10^8 K to achieve fusion reactions. Plasma Diagnostics provide measurements to characterize the plasma, which are necessary to understand the plasma state. These measurements are also utilized in the Plasma Control System to sustain the plasma under feedback control for long pulses or in steady state. The Control System performs not only plasma control but also functions as part of investment protection and for nuclear safety. Thus, these systems play the essential roles described above in ITER, and such functions are also expected within a DEMO fusion reactor.

Heating and current drive systems

Neutral beam injection heating and current drive

Principles

Neutral beam injection (NBI) is the workhorse of plasma heating in magnetic confinement fusion reactors. Its function is to deliver high-energy particles to the heart of the fusion plasma, which is achieved by firstly neutralizing a high-energy ion beam (in a gas cell neutralizer) and then injecting the neutralized particle beam into the fusion plasma. With proven results in legacy fusion devices such as JT-60U (Ikeda et al., 2006), JET (Duesing et al., 1987), and the LHD (Kaneko et al., 2003), which include achieving high performance plasmas having a (DT equivalent) energy gain factor, Q , of 1.25 and highly efficient current drive, the output expected of future NBI systems such as those of ITER and DEMO are highly anticipated.

The principles of NBI are illustrated in Fig. 1. In ion sources, plasmas are the medium from which the ions are extracted. The extracted ions are then accelerated in an accelerator to generate an ion beam. The accelerators used for NBI are electrostatic

Fig. 1 Principle of NBI using a negative ion source.

accelerators, the same type of accelerators used at universities. While beam energies are relatively low, ranging from a few 10 keV to 1 MeV, the current required for the ITER negative ion beam is in the tens of amperes, which is about six orders of magnitude higher than the current required for conventional accelerators. Big numbers require big solutions and thus a feature characteristic of the ITER NBI accelerators is that they use electrodes over 1 meter in length to accelerate multiple (1280) beamlets simultaneously.

Only atoms with a positive or negative charge (ions) can be accelerated by an electric field. However, electrically charged ions cannot be injected into plasmas of fusion devices because they will be deflected by a “cage,” that is, the magnetic field of the plasma. In the ITER NBI system, negative ion beams must pass through a gas cell where the excess electrons will be stripped from the negative ions so they can be injected into the plasma as a neutral beam—a beam that is not affected by a magnetic field. Once deeply inside the plasma, the neutral beam particles collide with ions and electrons and are re-ionized, becoming trapped in the magnetic cage. Through these repeated rapid collisions with ions and electrons in the plasma, energy is transferred to the plasma particles, a process which heats the plasma.

NBI will also play a key role in driving the plasma current required to sustain the fusion plasma. The established operating mode for tokamak devices is the pulsed mode, where current is applied to plasmas via electromagnetic induction by means of a transformer, and this also creates a component of the magnetic field used for plasma confinement. However, new fusion reactors are aiming for steady state, or continuous, operation. Neutral beams also provide momentum to the plasma and current drive by tangential injection into the torus. Through ionization by collisions with torus plasma electrons and ions, the toroidally circulating fast positive ions run around inside the circular chamber as large nested helices to make the magnetic cage stable (Dumont, 2021).

NBI systems were originally developed for use in fusion experiments in the 1970s (Dawson et al., 1971). The beam energies required for tokamaks at that time were ~ 30 keV. Accordingly, the very first NBI systems were based on positive precursor ion beams of hydrogen or deuterium, which were then converted in the injector to a “neutral” beam by neutralizing the ions in a gas cell neutralizer. As plasmas started getting larger and denser, beam energies of 0.5 MeV or more were required to inject the beams into the heart of the plasma. Fig. 2 shows the relationship between the neutralization efficiency of the ion beams and the beam energies. At beam energies above 200 keV, the neutralization efficiency of positive ion beams is essentially zero. On the other hand, negative ion beams can achieve a high neutralization efficiency of about 60% even at beam energies above 1 MeV. Therefore, it is crucial that the NBI systems of ITER and DEMO use negative ion beams for their primary beams.

Developing the negative-ion-based NBI for ITER

Performance requirements and technical challenges

Table 1 compares the values achieved by legacy NBI systems that use negative ion sources with the values required of the ITER and DEMO NBIs. Comparing the three main performance parameters of NBI systems—beam energy, beam current, and pulse duration—the large beam current required of ITER has already been achieved by the system developed for the Large Helical Device stellarator (LHD), but the beam energies and pulse durations demanded of ITER are very substantially greater. In other words, accelerating beams to 1 MeV or more for pulses lasting 3600 s are crucial engineering challenges for future NBI systems such as those in ITER or DEMO.

Negative ion source technological improvements

The negative ion sources used in JT-60U (Ikeda et al., 2006), JT-60SA (Ikeda et al., 2007), and the LHD (Kaneko et al., 2003) were designed to produce negative ions in an arc discharge plasma using filaments as the cathodes and the ion source walls as the anodes. Although negative ions are generated in arc discharge plasmas, their density is 1/10 or less than that of the positive ions (negative ion current density: 100 A/m²). The negative ion density had to be increased to obtain a high-current beam. Thus, in an effort to

Fig. 2 Dependence of the neutralization efficiency via charge exchange neutralization for positive and negative deuterium ions vs. the beam energy.

Table 1 Requirements of legacy and planned future NBI systems.

Parameters/Machines	LHD (Kaneko et al., 2003)	JT-60 U (Ikeda et al., 2006)	JT-60SA (Dawson et al., 1971)	ITER	DEMO
Status	Achieved		Under Development		In Planning
Beam energy (MeV)	0.18	0.5	0.5	1	1 ~ 1.5
Beam current (A)	40	22	22	40	~40
Pulse duration (s)	10	30	100	3600	Steady state
Technical issues				reduced maintenance frequency Twice a year	Continuous operation of appx. 1 year • RF-driven negative ion source • Cesium-free ion source • Plasma neutralizer • Photo (laser) neutralizer

increase current density, ion sources based on the “surface-ionization” principle were developed. Using this principle, atoms are converted into negative ions by receiving electrons at electrode surfaces, whose work function can be reduced by coating the ion-extracting electrodes with alkali metals, such as cesium, resulting in a high conversion rate (Leung et al., 1990; Hanada et al., 2006). By adding about a gram of cesium to the arc discharge plasma, a highly dense negative ion current density of 380 A/m² was obtained, which satisfies the current density required of ITER. The Max Planck Institute for Plasma Physics (IPP) in Garching, Germany, took a different approach to developing negative ion sources. They developed a new technology in which radiofrequency (RF) waves are injected through an external antenna to generate plasmas (Speth et al., 2006). Compared with the arc discharge method, RF ion sources have advantages such as

- requiring less maintenance and achieving higher reliability, removing the issue of filament lifetime,
- being clean because of the absence of evaporation of tungsten (filament material), removing the issue of cesium consumption by covering it with tungsten, therefore requiring no maintenance even after long operations.

Thus, RF negative ion sources were chosen as the baseline design for producing plasmas in the ITER negative-ion-based neutral beam injection source. The NBI design of ITER has eight RF drivers arranged in parallel, as shown in Fig. 3, to uniformly generate negative ions near the 1 × 0.6 m electrode surfaces and produce a negative ion current of 40 A. To make these RF negative ion sources a reality, research is ongoing at IPP on the ELISE test rig (Extraction from a Large Ion Source Experiment), which features an ion source one-half as large as ITER’s (4 drivers). With the goal of improving extracted ion current and stability, so far, a 190 A/m² deuterium negative ion beam has been successfully extracted for 2700 s, which is about 70% of the ITER requirement (Kraus et al., 2018). The key aspects of the ion sources will be tested on SPIDER (Source for the Production of Ions of Deuterium Extracted from RF plasma), an ITER-scale negative ion source at the Neutral Beam Test Facility (or NBTF) in Padua, Italy (Toigo et al., 2017). The NBTF started operations in June 2018 to demonstrate the required performance of ITER.

Accelerator technological improvements

Typical accelerators, such as those used at universities for particle experiments, are filled with an insulating gas like SF₆ to insulate the high voltage that is applied to the accelerator. However, because the beamlines of the ITER NBI system are straight, the accelerators are located directly in front of the plasma. Consequently, radiation from the fusion reactions in the form of neutrons and gamma rays flows into the NBI system through the beam injection ports. If the ITER NBI system were a conventional system that

Fig. 3 Schematic of the beam source designed for the ITER NBI.

used an insulating gas for applied voltages, a leakage current would flow through the insulating gas because of radiation-induced conductivity, resulting in decreased insulation performance and an exorbitant heating loss of over 100 kW. ITER overcomes this issue because its negative ion sources and accelerators are installed in a high vacuum, which insulates the system from the 1 MV acceleration voltages. As previously mentioned, for the ITER NBI to obtain sufficient current, the extraction takes place through 1280 beamlet openings distributed over a very large area (1×0.6 m).

In the early years of R&D for the ITER negative ion accelerator (around 1994), there were no inorganic insulator rings larger than 1 m to provide a sufficient insulation distance to ensure vacuum insulation for high voltages of 1 MV in the accelerator. Fiber reinforced epoxy (FRP) insulator rings were used, but they proved to be unsuitable to hold off 1 MV voltages due to frequent discharges along the vacuum side. Experiments showed that the discharges originated at the triple junction where three elements (metal, dielectric and vacuum) with different permittivities come in contact with one point. The electric field on such specific point tends to increase. However, through finite element analysis, it was possible to reduce the triple junction electric field to under 1 kV, resulting in the first successful hold-off of 1 MV for 1 h (Taniguchi et al., 2003; Inoue et al., 2006a).

The insulation distance between the electrodes was based on the standoff voltage data of Rogowski electrodes having a diameter of about 200 mm. The standoff voltage, V , was assumed to be proportional to the one-half power of the electrode gap (g), according to clump theory ($V = C g^{0.5}$). The proportionality factor, C ($= (V \times E)^{0.5}$), is a function of electrode area, and therefore electrodes having various surface areas were tested to derive a relation between the proportionality factor, C , and the electrode area, S . Results of these tests are illustrated in Fig. 4 (Tobari et al., 2017; Kojima et al., 2016). The voltage dependence on the surface area turned out to be rather weak, and thus vacuum insulation of a 1 MV accelerator became plausible.

When multiple negative ion beamlets are accelerated simultaneously in parallel, the beams are deflected due to space charge repulsion between the beams, which causes the beams to collide with the accelerating electrodes. The resulting high local thermal load can actually melt the electrodes, which can trigger degassing, and this, in turn, can cause breakdown discharges—a typical engineering issue with long pulse beam acceleration. By simulating the negative ion trajectory using 3D beam trajectory analysis, a novel method of creating an electric field to compensate the deflected beam trajectory by deliberately shifting the axis of the electrode aperture through which the beam passes was developed and tested at the National Institutes for Quantum and Radiological Science and Technology (QST) in Naka, Japan. The thermal loads on the electrodes, which in the past typically accounted for 25% of the acceleration power (acceleration current $\times$ acceleration voltage), were reduced to 10%. As a result, a negative ion beam of 0.97 MeV, 190 A/m^2 was successfully accelerated for 60 s (Kojima et al., 2017) and a beam of 0.5 MeV, 154 A/m^2 for 118 s (Hiratsuka et al., 2020), satisfying the requirements of ITER and JT-60SA, respectively.

Advanced technology development for NBI in demo and future reactors

The technical specifications of the NBI system for DEMO have not yet been finalized, but a logical extrapolation of ITER NBI technology is assumed, with estimated values shown in Table 1. The most substantial change in the step from ITER to DEMO is the neutron and gamma radiation doses. The radiation intensity of DEMO is expected to range from several to 10 times higher than

Fig. 4 Experimental measurements of the proportionality factor, C , used to determine standoff voltage in a vacuum-insulated configuration, as a function of the electrode surface area, S .

that of ITER. To prevent the vital functional materials used in the ion source from degrading (such as the permanent magnets and ceramic insulator rings), shielding must be installed in the beamlines. A design has been proposed in which shielding is installed in the empty spaces created by focusing the multiple beams accelerated by the large-area electrodes into several converging beams (Inoue et al., 2006b).

DEMO must also prove to be economically efficient to demonstrate the commercial viability of fusion and so an NBI system efficiency (=NB injected power/NB operating power) of 50% or more is required to reduce the circulating power of the facility (Okano et al., 1997). NBI system efficiency is dependent on neutralization efficiency, which has a maximum of ~60% in the case of conventional gas neutralization cells. ITER's NBI system has a system efficiency of about 40%. A need for alternatives to gas cell neutralizers has therefore been recognized. Plasma neutralizers (neutralization efficiency: 80%) are a possible candidate and, accordingly, proof-of-principle tests have been conducted (Hanada et al., 2004). Another promising candidate is the photo (laser) neutralizer, which, in theory, could achieve a neutralization efficiency of 90% (Inoue et al., 2006b).

In terms of DEMO's beam acceleration, using electrostatic accelerators similar to those of ITER, in addition to vacuum insulation of 1–1.5 MV, gas insulation, involving a gas flow into the ion source to produce ions, has been verified (Inoue et al., 2006b). Operating the negative ion sources stably during the continuous 1-year operation campaign required of DEMO will entail the development of advanced technologies, ideally technologies that reduce maintenance frequency (RF-driven negative ion sources) and do not require seeding with cesium.

Radio frequency heating and current drive

Principles

Just as with communication devices such as mobile phones, radios, and televisions, RF heating and current drive systems also use radio frequencies, in the range from a few MHz to several 100 GHz, to heat and drive plasmas. The heating principle is similar to that of the microwave oven. In magnetically confined plasmas, electrons and ions spiral around a magnetic line of force (hence the name cyclotron). Energy is fed to these charged particles in the form of electromagnetic waves at frequencies that match the oscillations of the different particles inside the plasma—the resonant cyclotron frequency $\Omega_{i,e} (=|q_{i,e}| \cdot B / 2\pi \cdot m_{i,e})$: ion, electron charge, B : magnetic field, $m_{i,e}$: ion, electron mass). The charged particles in the plasma absorb the electromagnetic energy and as a result, increase in kinetic energy. By way of collisions, ions will in turn transfer the absorbed energy to electrons, thus heating the plasma. Radiofrequency waves are also used to induce currents in the plasma in a technique known as radio-frequency current drive. RF waves are injected into the plasma and the consequent wave electric field accelerates the electrons as the wave and particles move together around the torus, resulting in the electrons developing a net motion, or current (Fig. 5: Landau damping).

RF heating systems have been used in various magnetic confinement fusion devices, and particularly in tokamaks and stellarators. RF heating systems are composed of an RF source, a transmission system for transmitting the generated RF power to the vacuum vessel, and a coupling system (antennas and launchers) installed in the vacuum vessel port to inject the RF power into the plasma. RF heating systems have the advantage of being less susceptible to the effects of radiation (such as from neutrons) because their RF sources can be installed far away from the plasma, which may be advantageous in future fusion reactors. There are three kinds of RF heating systems such as ICRF, LHFR and ECRF.

Ion cyclotron and lower hybrid radio frequency systems

An ion cyclotron radio frequency (ICRF) system uses commercially available tetrodes with MW-level output power, which were already available by the second half of the 20th century. In addition, radio/TV broadcasting equipment can be used for the transmission systems. The JET (EU) and TFTR (US) tokamaks have also exploited ICRF heating extensively to explore fusion plasma

Fig. 5 Landau damping. Particles traveling at a speed approximately the same as the phase velocity of the wave can exchange energy by interacting with the electric field of the wave. The event is called as Landau damping.

performance in the parameter range relevant to fusion power production (The JET Team, 1998; Phillips et al., 2000). Based on these experience, ICRF heating has developed into a mature RF heating technology. In the MHz range, however, the wavelength within the plasma differs substantially from that in vacuum. Therefore, the design of a suitable RF matching system is important in designing a suitable ICRF antenna in order to obtain a good coupling with plasma. Consequently, ICRF antennas must be installed very close to plasma boundaries, which raises the engineering challenges of how to mitigate the high thermal loads from the plasmas and the effects of neutron irradiation on a high voltage insulator. Thus, there are significant challenges in the development of ICRF antenna and matching systems for ITER or DEMO reactors, and major design and R&D activities are underway to address these challenges for ITER (Hoang et al., 2009).

In lower hybrid radio frequency (LHRF) systems, klystrons are used for the RF sources. In the case of JT-60UI, current drive in the peripheral region of plasmas was successfully demonstrated using MW-level klystrons. However, as with ICRF systems, the launchers of LHRF systems also must be installed near the plasma to ensure efficient coupling of the waves to the plasma, and this raises the engineering challenges of not only mitigating high thermal heat loads from the plasmas but also of limiting impurity contamination into plasma (due to sputtering of the plasma-facing material of the launchers). Novel solutions, such as the passive-active multijunction launcher (Kasugai et al., 1998; Hillairet et al., 2013), are being investigated to address the issues associated with applying LHCD technology in the reactor plasma environment.

Electron cyclotron radio frequency system

An electron cyclotron radio frequency (ECRF) system uses high-frequency RF waves in the range of 100 GHz. In this frequency range, RF power is generated by a gyrotron, transmitted either by waveguides or quasi-optical (via a mirror arrangement) means toward a vacuum vessel port and finally injected into plasma by a launcher installed at the port. There are two types of transmission lines; by means of waveguides and quasi-optical mirror. The waveguide transmission is commonly applied to the ECRH system of many machines and ITER (Cengher et al., 2017; Omori et al., 2011). Power density can be increased with focusing the beam shape by using metal mirrors. Thus, RF power of about 1 MW can be injected through a relatively small aperture (a few to several tens of centimeters square) and allows the launcher mirrors to be installed at some distance from the plasma, with improved potential for shielding and cooling than is the case for other RF systems. Further, these mirrors are rotatable and can control the direction of RF power injection, which allows the location of power deposition to be controlled selectively, from the center to the edge of a plasma for plasma heating and current drive by taking advantage of both cyclotron resonant and Doppler-shifted absorption, as discussed by Dumont (2021). Taking the advantage of this feature, neoclassical tearing mode instabilities (This instability is caused by a magnetic island induced by magnetic fluctuation.), which cause plasma disruptions (collapse events of plasma due to instabilities) due to the formation of magnetic islands in the peripheral region of plasma, can be suppressed. The mitigation and the stabilization of magnetic islands by performing local current drive within magnetic islands can only be accomplished using ECRH systems due to the narrow spatial localization of the wave absorption in the plasma.

Because of these advantages, ECRH was selected as the single RF heating system for JT-60SA (Kobayashi et al., 2009), a joint Japan and EU tokamak which is expected to achieve plasma operation in 2021. The ITER project plans to install both an ECRH and an ICRF system, each capable of launching 20 MW of power into the plasma, with later expansions of this capability possible.

As an example of an initial reactor-grade ECRH system, an overview of the ITER ECRH system configuration is illustrated in Fig. 6. High power microwaves at 170 GHz are transmitted over a distance of ~ 100 m using several arrays of oversized cylindrical corrugated waveguide and the power is focused into the plasma by means of groups of mirrors situated in five launchers, one situated on the tokamak midplane and the other four situated in upper ports. To generate the 24 MW of source power, providing an injection power of 20 MW, ITER will use 24 “gyrotrons” each generating 1 MW of RF power at 170 GHz. An example of an ITER gyrotron is shown in Fig. 7, while a schematic cross-section of the device is illustrated in Fig. 8. The gyrotron concept, in which stimulated emission is generated and amplified by a relativistic electron beam passing through a cylindrical cavity, was invented in the 1960s in Russia and the United States (Gaponov, 1959; Schneider, 1959). The technology has been under development since that time with several design improvements and substantial increases in power generation in the last two decades.

One can understand the basis operating principle of the gyrotron from the schematic in Fig. 8: the electron gun at the bottom of the gyrotron extracts a “hollow” beam of electrons having 70–80 keV of energy and this is accelerated in the magnetic field generated by the superconducting coils; the beam is subsequently injected into the cavity resonator, where the rotational energy of the electrons is converted into RF energy by means of the electron cyclotron maser principle (Gaponov, 1959; Schneider, 1959); the RF excited within the cavity has a complex electromagnetic field distribution which is then converted into a Gaussian power

Fig. 6 An overview of the ITER ECRH system configuration.

Fig. 7 An example of an ITER gyrotron, one manufactured in Japan.

distribution by a mode converter installed at the exit to the cavity, and the resulting RF beam is emitted from the gyrotron. The electron beam component retaining the energy fraction not converted into RF power is transmitted to the collector located at the top of the gyrotron, where the residual beam power is recovered and/or thermally dissipated.

Research and development of gyrotrons for fusion plasma heating has been underway since the early 1980s, and a high power, long pulse capability has been achieved by overcoming several specific challenges: (1) high-order mode oscillation due to the high frequency of operation; (2) improvement of gyrotron operational efficiency; and (3) the need for vacuum windows to allow low loss transmission of MW-level RF energy from the gyrotron to the transmission system. Development of sophisticated numerical codes capable of modeling nonlinear cavity oscillations (Sakamoto et al., 1996) allowed the derivation of conditions for stable mode oscillation, eliminating competing modes. This analysis provided the basis for the manufacture of the internal components with precision machining on the order of microns. Combined with the use of position control of the electron beam injection into the cavity, conditions for stable oscillation of the 170 GHz gyrotrons in ITER were established. The ITER R&D activities also demonstrated that by insulating the gyrotron collector from the gyrotron body and applying a high voltage to the body of the collector to decelerate the electron beam and recover its kinetic energy, gyrotron operation efficiency could be increased to 50%.

Fig. 8 A schematic cross-section of the Gyrotron device.

Development of a vacuum window capable of handling high power density with low losses in long pulse operation has been a long-standing constraint on the application of ECRH to fusion plasma heating, particularly with a perspective toward its application in fusion reactors. In earlier experiments an alumina or a sapphire disk was used for gyrotron vacuum windows, but the transmitted power was limited to a few hundred kW for pulses of less than a second, even with improved cooling structures. In 1990, a high-quality, large-diameter (~ 100 mm) synthetic diamond disk produced by means of CVD (plasma chemical vapor deposition) became available (Brandon et al., 2001). By using vacuum windows formed from these synthetic diamonds, which have about five times higher thermal conductivity than copper and therefore allow efficient edge cooling of the disk, 1 MW steady-state gyrotron operation could be demonstrated. The high mechanical strength of diamond also allows very thin windows, ~ 1 – 1.5 mm, “tuned” to the gyrotron radiation wavelength to be fabricated, minimizing reflection and absorption losses.

Developing prototype reactor ECRF systems

In case of both ICRF and LHRF system, their antenna design is the most critical issue because of high thermal radiation and large neutron flux from plasma, which lead the damage on the antenna front. Although the technical issue exist, ICRF is a candidate of Heating and Current Drive system of DEMO (Federici et al., 2019). On the other hand, an ECRF antenna requires only a small aperture to inject RF power and, in this sense, ECRF is a promising candidate of RF heating system for a DEMO reactor. The various design options for DEMO are currently under development, ranging from high-field tokamaks (11 T) to devices with more modest fields (around 6 T, which is close to ITER’s magnetic field strength of 5.3 T) with the aim of reducing the construction cost. Considering ECRF over this range of magnetic fields, an ECRF system at 300 GHz would be required for a high-field design, while a frequency close to 200 GHz would be required in the latter case. Numerous technologies and advances acquired in the development of the ITER gyrotrons can be applied to these future designs, while further increasing their output power, perhaps into the range of 1.5–2 MW. Regarding to the development of the launcher for DEMO, the use of a movable launcher mirror to control the injection angle of the beams for changing the location of RF power deposition is unlikely to be practical in DEMO and fusion reactors due to the significant increase of neutron loading. Instead, a gyrotron capable of multi-frequency oscillation could be used to control the resonance location of RF power in plasmas by variation of the RF frequency, since the resonant location for absorption of the RF power depends on both the wave frequency and the magnetic field. Initial developments in multi-frequency gyrotrons (Ikeda et al., 2017) have demonstrated the concept successfully and, while significant further development is required for their application to CW high power operation in future reactors, this would provide the possibility of varying the radial deposition location while simplifying the launcher design.

Fuelling systems

Introduction

Fuel supply systems, which are designed to maintain the required operational plasma density and to replenish the DT fuel consumed in fusion reactions, mainly consist of a gas injection system (GIS [Boccaccini and Day, 2021](#)) and a pellet injection system (PIS). These systems are capable of supplying fuel particles (H, D, T) and impurities (Ne, Ar, etc.) into the vacuum vessel, which is necessary for plasma burn control. These fuel and impurity species are provided by the storage and delivery system of the tritium plant, as described by [Boccaccini and Day \(2021\)](#). A further function now incorporated into the fuel supply system which is not directly related to the supply of fuel particles, but in tokamak experiments is just as important, is the disruption mitigation system (DMS [Lehnen et al., 2018](#)), which rapidly (~ 10 – 100 ms) injects a large number of particles into the plasma when the plasma control system flags an approaching disruption. The operation of the DMS is designed to mitigate the effects of thermal loading and electromagnetic forces, and to suppress the generation of runaway electron (RE) beams associated with a sudden plasma quench.

In this article, the features of the PIS and DMS, which play key roles in the operation of large fusion devices, and the basic technologies of the respective systems are described. The GIS, which is the standard fuel supply system for small to medium scale machine, employs piezo-electric actuating valves or mass flow controllers compatible with nuclear environment. In ITER, newly developed mass flow controller is chosen for mass flow control.

Pellet injection system (PIS)

As magnetic fusion devices have increased in physical size, it has become increasingly challenging for the GIS to supply fuel particles to the center of the plasma efficiently, since injected gas particles are ionized at the plasma edge and must be transported to the center by (collisional and turbulent) transport processes within the plasma. Experiments showed that the required plasma density control efficiency could not be achieved. Thus, in many fusion devices, pellet injection systems capable of injecting solid, high-density fuel in the form of small pellets of frozen hydrogen or deuterium play a central role in controlling plasma density. It should be noted that a significant R&D issues for fusion reactors (including ITER, of course) is that tritium injectors must sustain cryogenic operation in spite of the heat generated by the radioactive decay of tritium (which is, of course, not the case for hydrogen and deuterium injectors).

In fusion plasmas, particles injected into the plasma become ionized and are subjected to plasma-induced forces which drive the cloud of particles resulting from the ablation of the pellet from the high field side (HFS) to the low field side (LFS), an effect associated with the magnetic field in the plasma. Therefore, when injecting pellets from the LFS, the injection speed must be extremely fast (> 2000 m/s) to penetrate deeply into the plasma and to overcome this process, which not only complicates the system but also makes it difficult to support continuous operation at the pellet injection frequencies of 1–10 Hz required to meet the fuelling requirements. In many fusion devices, including ITER, pellets are injected from the HFS side, which can supply fuel particles at a sufficient rate to the center of the plasma even at low injection speeds (300–500 m/s), which is favorable in comparison to the injection velocity requirements from the LFS side.

A brief description of the pipe gun pellet injector capable of both generating and accelerating pellets is given below, followed by a description of the main features of the PIS, i.e., the extruder which generates and injects solid fuel and the accelerator which accelerates pellets to the required speed.

Pipe gun pellet injector

The simplest type of pellet injector is the pipe gun injector. These have a proven track record and have been used in fusion devices for over 30 years. As shown in [Fig. 9](#), the section of the cylinder of the pipe gun without the extruder is cooled below the triple point of

Fig. 9 Pipe gun pellet injector concept and application to Shattered Pellet Injection DMS. From Baylor LR, et al. (2019) *Nuclear Fusion* 59: 066008.

the fuel gas and the fuel gas is then introduced to form pellets directly. High-pressure gas is supplied from behind to detach the pellets and accelerate them to the required speed. Thus, pipe gun injectors are not suitable for continuous fuel particle supply and are mainly used for intermittent operations such as injecting impurity pellets.

Extruder

Extruders can be divided into two main types, batch and continuous, also known as piston and screw extruders, respectively. With piston extruders, fuel particles are pre-solidified and stored in the cylinder, and the solid fuel is injected by the piston. With screw extruders, as shown in Fig. 10, fuel gas is supplied to the extruder which is cooled below the triple point and the solidified fuel is continuously injected by a screw mechanism. Using this principle, solid fuel can be injected continuously as long as there is a supply of fuel gas and coolant.

Accelerator

There are two types of pellet accelerators, the pneumatic gas gun type, driven by compressed gas, and the centrifuge type, driven by centrifugal force. With pneumatic gas gun accelerators, a solenoid drives a pellet cutter back and forth, solid fuel on a ribbon ejected from the extruder is loaded into the cylinder, and the compressed gas accelerates the pellets to the required speed. With centrifuge accelerators, the solid fuel injected from the extruder is cut into the required size by a pellet cutter, the fuel is dropped into a pellet catcher at the center of a centrifugal accelerator, and then accelerated to the required speed by using centrifugal force.

ITER, for example, uses the gas gun method, which has been proven in fusion devices such as the DIII-D tokamak and the LHD stellarator. Research and development in support of the ITER system is being conducted at the Oak Ridge National Laboratory in the U.S. using equipment at 1/5th scale.

Disruption mitigation system (DMS)

Current fusion devices such as JET and the ASDEX Upgrade have used Massive Gas Injectors (MGI) that use high pressure gas valves (52 bar D_2 or Ar/D_2 :0.1/0.9 in JET) driven by piezoelectric or eddy current forces for their disruption mitigation system. These have

Fig. 10 Twin screw extruder developed for W7X. From Baylor LR, et al. (2019) *Nuclear Fusion* 59: 066008.

succeeded in mitigating the effects of thermal loading and electromagnetic forces caused by plasma disruptions by injecting Ne, Ar or a gas mixture involving one of these impurities and D₂. However, JET experiments verified that MGI did not suppress or mitigate Runaway Electron (RE) beam generation because the penetration of injected particles into the plasma was insufficient. Thus, ITER will use shattered pellet injectors (SPI)—installed in seven locations around the tokamak—capable of injecting a larger number of particles than MGI into the center of the plasma. See Fig. 11.

SPI is a pipe gun driven system developed at Oak Ridge National Laboratory. Solid pellets made of argon, neon, deuterium, or a mixture of these materials fly through a guide tube at a speed of 300 m/s to 500 m/s in order to reach the edge of the plasma. These pellets are crushed by a shattering tube installed at the end of the guide tube before being injected into the plasma. Although the effectiveness of SPIs have been verified in the DIII-D device, the ITER Organization has taken the lead to acquire the data necessary to extrapolate the data to the ITER scale, and is equipping the JET, KSTAR, and ASDEX Upgrade devices with SPI systems to explore the effectiveness of this approach to disruption mitigation in experiments starting in 2020.

Fueling systems for a nuclear device face significant additional challenges in sustaining the required fuel mixture to maintain high fusion gain operation under quasi-stationary conditions compared to the demands made on fueling systems for existing devices. Therefore, successful development and implementation of fueling and disruption mitigation systems are critical to the success of ITER operation and will establish the technological basis both for the DEMO project and for future fusion power plants.

Plasma diagnostics

Introduction

Magnetic confinement reactors are equipped with an array of various diagnostic instruments to provide the measurements necessary to control, evaluate, and optimize plasma performance (both to operate the reactor safely and stably and to maintain high fusion power for a long period of time) and to further the understanding of plasma physics (to develop better operating modes). Plasma diagnostics serve the following four main functions.

- #1: Protect reactor systems and components by ensuring their safety and functionality.
Measuring the surface temperature of plasma-facing components, such as the blanket or divertor, to verify that the temperature is within the allowable range, is but one example.
- #2: Control plasma
Parameters necessary to control and maintain dense, high-temperature plasmas, such as plasma current, electron density, and the location of the last closed flux surface, are measured throughout the entire process from start-up and steady-state operation to shutdown.
- #3: Evaluate plasma performance
Parameters used to evaluate plasma performance, such as assumed confinement improvement H_{Hy2} , normalized beta β_N , normalized density n_e/n_{GW} , and bootstrap current fraction f_{BS} , are determined to create optimal operation scenarios. Reference Wade (2021) explains these parameters.
- #4: Enhance the understanding of plasma physics
Diagnostic instruments are used to establish the underlying physics of fusion plasmas, such as determining the responses to plasma instabilities and the basis for heat and particle transport. Diagnostics are indispensable tools in terms of developing fusion reactors: they provide the scientific foundation upon which reactor design tools and operation simulators are based.

A well-known example of function #3, evaluating plasma performance, relates to the T-3 tokamak from the former Soviet Union. Soviet scientists announced that the T-3 could produce plasmas with temperatures above 1 keV, but doubts were cast on the

Fig. 11 DMS system to be installed in ITER equatorial port.

reliability of their plasma temperature evaluation method. British scientists at Culham had perfected a reliable method for measuring very high temperatures based on the then novel method of laser light scattering on plasma electrons (Thomson scattering). They brought their Thomson scattering apparatus to the Soviet Union to validate the T-3 performance, which proved successful and confirmed the high temperatures of the T-3 plasmas (Peacock et al., 1969). This blew a fresh wind through fusion research worldwide in the 1970s and was a major breakthrough for the tokamak concept. A quintessential example of function 4, enhancing the understanding of plasma physics, would be sawtooth instabilities. Sawtooth instabilities are relaxations commonly observed in the core of magnetically confined plasmas, which occur quasi-periodically and cause a sudden drop in the temperature and density in the center of the plasma. A theory was created to explain the mechanism of these sawtooth instabilities, that is, until new diagnostics provided contradictory data, which ultimately improved upon and made the theory more concrete. The full story is summarized in reference Wesson (2011).

Various types of plasma parameters need to be measured to ensure functions #1 to #4: Plasma current (I_p), plasma position and geometry, energy (W , β), magnetic field (B), electric field (E), electric potential (ϕ), radiant energy (P_{rad}), ion (i)/electron (e) density (n)/Temperature (T)/flow velocity (v)/distribution function (f), ion species, fusion power (P_{fus}). Further, non-contact measurements are required because of the high temperature of fusion plasmas. Plasma diagnostics can be classified according to their measurement method as follows.

- *Electrical/magnetic diagnostics*: magnetic probes (I_p , LCFS, V_{loop} , β_p), Langmuir probes (n_e , T_e).
- *Systems based on propagation characteristics of electromagnetic waves*: interferometers (n_e), polarimeters ($n_e B$), reflectometers (n_e).
- *Systems based on radiation/scattering of electromagnetic waves*: CYCLOTRON emission diagnostics (T_e), scattering diagnostics (n_e , T_e , n_{α} , $f(v_i)$).
- *Plasma emission diagnostics*: passive spectroscopy (impurity, Z_{eff} , T_i , n_H/n_D , n_T/n_D), active spectroscopy ($B_{\text{pol}}/B_{\text{tor}}$, v , Z_{eff} , n_{He}/n_e), bolometers (P_{rad}).
- *Particle/neutron diagnostics*: electrostatic energy analyzers (n_T/n_D , ϕ), neutron diagnostics (P_{fus} , n_T/n_D), lost alpha particle diagnostics.
- *Plasma-facing and operational diagnostics*: thermocouples, pressure gages, residual gas analyzers, visible light cameras, IR cameras, erosion monitors.

As listed above, a variety of physics principles and technological techniques are used to ensure function #1 to #4. Multiple instruments may be combined to obtain certain specific plasma parameters. For example, a highly accurate determination of safety factor can be calculated by combining measurements made by magnetic probes, interferometers, polarimeters, Thomson scattering diagnostics, and active spectroscopy.

ITER diagnostic systems

ITER will be equipped with 58 diagnostic systems (Vayakis et al., 2012; ITER Physics Expert Group on Diagnostics and ITER Physics Basis Editors, 1999; Donne et al., 2007), and will measure several physical quantities for physics research purposes. Many of these single physical quantities will be measured by using multiple diagnostic instruments having different measurement principles, hence the large number of diagnostic systems.

Each individual diagnostic instrument must be designed in consideration of the following: (1) radiation heat ($< 1 \text{ MW/m}^2$) and nuclear heat ($< 10 \text{ MW/m}^3$) from the plasma, (2) electromagnetic forces ($< 100 \text{ T/s}$) and acceleration load due to plasma disruptions, (3) electromagnetic noise, (4) effects of neutron and gamma irradiation on optical and electronic devices, (5) neutron and gamma shielding for optical and electronic devices, (6) minimization of shutdown dose rate (ALARA (as low as reasonably achievable) principle to minimize exposure to humans), (7) containment of activated pressurized cooling water (application of nuclear pressure vessel regulations), (8) ensuring tritium confinement boundaries are maintained in case of accidents such as earthquakes or fires (e.g., vacuum windows and vacuum electrical feedthroughs), (9) structural designs that are based on nuclear energy standards, (10) position alignment, calibration, and maintenance methods that can be implemented in a radiation environment.

In particular, (4) "the effects of neutron and gamma irradiation on optical and electronic devices" is of special importance for ITER (and any subsequent fusion reactors, such as DEMO). Because of the harsh environment inside the ITER vacuum vessel—where many of the detectors are located—the diagnostic systems must cope with a range of phenomena not previously encountered in diagnostic implementation, while performing with great accuracy and precision. (Thermocouples, bolometers, electromagnetic and neutron diagnostics will be heavily affected by radiation.) The levels of fast neutron flux, gamma ray dose rate, and neutron fluence are respectively about $1 \times 10^{17} \text{ n/m}^2\text{s}$, $\sim 100 \text{ Gy/s}$, and $2 \times 10^{24} \text{ n/m}^2$ behind the shielding blanket. In addition, the diagnostic instruments must be designed in consideration of radiation-induced conductivity (RIC) (Zinkle and Hodgson, 1992; Hobbs, 1994), radiation-induced electrical degradation (RIED) (Hodson, 1992; Shikama and Pells, 1994), radiation-induced thermoelectric sensitivity (RITES) (Nishitani et al., 2004), and radiation- and temperature-induced electromotive forces (RIEMF, TIEMF) (Vayakis et al., 2003). What is more, electronic devices located outside the vacuum vessel (detectors, amps, cameras, etc.) must be radiation hard. The electronics of vital equipment necessary for plasma operation must be shielded so that the total ionizing dose is less than 1 Gy , the equivalent neutron fluence is less than $1 \times 10^8 \text{ n/cm}^2$, and the total neutron flux is less than $0.01 \text{ n/cm}^2\text{s}$ (EEE, 2017). Optical elements such as windows, lenses, and optical fibers must be designed in consideration of the irradiation effect, because their transmittance changes with neutron and gamma irradiation. R&D results for ITER are summarized in Reference (Campbell et al., 2019).

To expand on (5) “neutron and gamma shielding” and (10) “alignment and maintenance procedures,” recall that magnetic confinement reactors use non-contact measurement methods to measure electromagnetic waves and light. Although there are holes in the shielding to allow electromagnetic waves and light to propagate, the optical path must be in the form of a labyrinth to prevent the high neutron flux from leaking out of the vacuum vessel through these holes. The mirrors installed at the bends of the labyrinth optical path are, along with the shielding, located inside the vacuum vessel, where they will become extremely hot because of nuclear and radiation heat. Thus, these components located in-vessel must be made of metals having excellent cooling properties. Glass substrate lenses, prisms, or mirrors cannot be used. This means that optical components of ITER diagnostics are installed inside the vacuum vessel and their transmission optics are to be composed only of water-cooled planar or curved metal mirrors. Besides, deposition of impurities such as beryllium and tungsten on the mirrors are also problem because the deposition causes reduction of reflectance and change of spectral reflectance. Such a feat has never before been achieved by any other experimental device. There are also significant constraints on how these mirrors can be maintained, replaced, or adjusted. The ITER vacuum vessel will be radioactive and inaccessible to humans. The shielding to which the mirrors are mounted weighs more than 20 t, and thus the optics in the vacuum vessel needs to be designed without relying on maintenance, refurbishment or replacement demanding remote-handling removal of 20 t shielding blocks. Also, in consideration of the electromagnetic loads during plasma disruptions, the mirrors are fixed to a rigid mirror mount that cannot be adjusted angularly, except for some special cases. The inability to maintain or replace optics together with the inability to adjust front-end optics angles represent a major challenge in diagnostic development, so as to ensure reliable operation over the lifetime of the experiment. One of techniques developed for the mirrors is in situ mirror cleaning system (Litnovsky et al., 2019). The in situ mirror cleaning system uses plasmas generated by radio frequency to sputter contaminants from the mirror surface.

Diagnostic systems for DEMO

Studies on the diagnostics for the DEMO reactor have begun (Donne et al., 2012; Todd, 2014; Biel et al., 2015, 2019), but no specific designs have been decided. What is certain, though, is that the number of diagnostic instruments installed in DEMO will be significantly less than in ITER or other devices currently in operation. The space in the blanket that can be allocated to diagnostics must be limited to ensure a tritium breeding ratio (TBR) of one or more. The type of instruments that can be installed for front-end optics will be constrained due to the harsh environment (such as neutron radiation, accumulation of impurities and dust, and high temperatures). The “control knobs” for self-sustaining burning plasmas are also limited, so potentially having only a diagnostic that determines whether the plasma is in steady state or not may be sufficient. The following instruments are considered to be the minimum requirements: (1) magnetic diagnostics for plasma current, position control, and for detecting instabilities, (2) line-averaged electron density measurement to control the fuel supply, (3) spectroscopy for impurity and helium monitoring, and (4) neutronic diagnostics to measure the ratio of fuel to total neutron yield. Burn control and control of the detached divertor plasma are also very important factors, but the selection of the minimum instrumentation required for these controls is dependent upon the results of ITER experiments.

Other items that must be factored into DEMO diagnostics are radiation hardness, high thermal loads, high displacement per atom due to neutron flux, measurements during steady-state operation, deposition of impurities and dust, relativistic effects on electromagnetic wave propagation characteristics, attenuation of measurements due to the blanket, and compliance with blanket maintenance procedures. As a specific example relevant to the requirements for DEMO magnetic measurements, magnetic diagnostics in present devices record data by using the signals from pickup coils via integrators. However, since DEMO will operate in steady state for periods of several months, using integrators will result in large errors (integration systems can measure reliably only for periods of up to 1000 s). It is also entirely possible that Hall effect sensors cannot be used because of the radiation environment. Hence, either these integrator errors will have to be corrected somehow, or the in-vessel conditions may have to be estimated from data gathered by Hall effect sensors installed outside the vacuum vessel. Even if the errors of the pickup coils can be corrected, issues may arise from high thermal loads and irradiation effects if the coils are located near the plasma. And if the pickup coils are installed behind the blanket, the magnetic field would be shielded by the blanket, making plasma vertical position instabilities difficult to detect. Even if all of these issues have been resolved, it begs the question: how would pickup coils installed behind the blanket undergo maintenance. These challenges are not limited to only magnetic diagnostics but common to most plasma diagnostics. Considerable R&D is required to develop a reliable diagnostic capability for DEMO and beyond. ITER will provide significant input to this R&D, but it is likely that a variety of developments will have to be pursued in parallel to establish the science and technology foundations to design and construct robust diagnostics for DEMO.

Plasma control

Introduction

A magnetically confined plasma is a complex state which cannot be sustained without a sophisticated feedback control system. In addition, free energy which is available within the plasma tends to generate turbulence and magnetohydrodynamic (MHD) instabilities which reduce plasma confinement quality. In a thermonuclear plasma, with significant fusion power produced by deuterium-tritium reactions, further control requirements are imposed in ensuring that the fusion power can be sustained for extended periods, or even continuously.

Plasma control methodology does not differ from that applied in control systems found in all technologies: it requires a means for measurement of the parameter to be controlled (in the fusion plasma environment via "diagnostic" systems), an "actuator" to modify the required parameter, which for fusion plasmas might be heating and current drive systems, fueling systems or magnetic coils, and an electronic system to determine the required action via an analog or, now more commonly, digital computation. Particular challenges for magnetically confined thermonuclear plasmas (i.e., plasmas primarily heated by DT reactions) include the fact that the physical parameters to be controlled must, in some cases, be derived from multiple diagnostic measurements, which must themselves be adapted to the fusion nuclear environment, and that only a limited number of actuators are available to control numerous parameters, and so each actuator might be shared among several control functions.

Among others, there are three functional requirements for the plasma control: they are (i) plasma control to achieve and maintain high fusion power output stably for long period as described above. This is to be achieved by the PCS. And moreover, (ii) investment protection, and (iii) nuclear safety. These functions of plasma control are incorporated in the control system of a fusion reactor. Failures of such plasma control system lead to conditions which almost invariably tend to reduce fusion power, or extinguish the plasma.

According to the functions required above, 3 levels of hierarchies are applied in the plasma control systems in the nuclear environment of ITER (Aymar et al., 2002; Donné et al., 2021) as an example. The three levels of systems as follows have differing functions and separate implementation:

- (i) Plasma Control System (PCS),
- (ii) Investment Protection System (ICS), and
- (iii) Safety Protection System (Central Safety System, (CSS) in ITER).

Plasma control system (PCS)

The fundamental variables most relevant to achieving the high values of fusion gain, Q , required in a fusion reactor are the ion temperature at the plasma core (T_i), plasma density (n_e), and energy confinement time (τ_E). In particular, the confinement time involves a complex interplay of various distributed quantities and states of the plasma, which are mainly determined by the toroidal magnetic field, position and shape of the plasma, total plasma current, the current density profile, etc. In addition, the fundamental quantitative variables of the plasma are the shape of the last closed flux surface; plasma current density profile; electron density profile (or n_e at a representative point); ion temperature profile (or T_i at a representative point); and electron temperature profile (or T_e at a representative point). All of these physical quantities have associated fusion reaction rates (and their distributions in energy). And so all of these factors must be controlled, either directly or indirectly, to control the fusion output.

These plasma control variables can be determined by directly measuring or processing the signals measured by the diagnostic instrumentation. Rudimentary electromagnetic measurements include plasma current, coil current, poloidal magnetic field, poloidal magnetic flux, toroidal magnetic flux. From these measurements, various equilibrium quantities such as the current, position, and shape of the plasma can be obtained. Using these equilibrium quantities and other physical quantities, such as plasma density, electron and ion temperatures, number of neutrons emitted, electromagnetic radiation from the plasma, impurities, plasma internal magnetic field distribution, the three fundamental variables n_e , τ_E , T_i , (for determining Q value) can be calculated.

Furthermore, plasma behavior determined by fusion reactions (Kurihara et al., 2008) is characterized by:

- (a) high self heating (70–90%) and high bootstrap current fraction, the interactions of which make for a self-sustaining system;
- (b) a system in which local and global interactions and fluctuations with different time scales (MHD, turbulence) intertwine. A wide range of time constants are also prevalent, for example, ideal MHD (typical time scale in the order of microseconds), energy confinement time (seconds), current diffusion time (in the order of hundreds of seconds), and particle wall saturation (in the order of thousands of seconds). ITER is expected to operate in a range of "advanced" plasma regimes in order to meet its mission goals. For example, in "ELMy H-mode" plasmas, MHD instabilities localized near the plasma edge (ELMs) that produce periodic loss of energy from the edge plasma must be controlled, while in plasmas having negative magnetic shear, which are characterized by internal transport barriers, the current profile shape must be controlled for stable long-pulse operation (ITER Physics Expert Group on Disruptions, Plasma Control, and MHD et al., 1999; ITER Physics Expert Groups and ITER Physics Basis Editors, 1999).

Turning to the plasma control methods themselves, PCS of fusion reactors must have the capability to;

- (a) adjust actuator commands in response to various changes in the plasma to sustain the planned operation; and
- (b) to terminate the plasma in a controlled fashion in the event a plasma cannot be adjusted back to the standard operating mode.

Using feedback control, plasmas must be precisely maintained in, or adjusted to, their optimal state to achieve high fusion performance, which requires the use of highly customized computer systems for real time control (Kurihara, 1993). Some control methods combine control techniques, for example by switching between:

- (a) Simple setup control: a waveform of actuator outputs are given directly in advance (pre-programmed waveform: ppw) and executed during plasma discharges, and
- (b) Tracking control: a waveform of certain plasma parameters are given in advance (ppw) and actuators are controlled to follow these pre-programmed plasma parameter waveform.

In the following are some example of plasma control for events with specific time scales.

Fast control of plasma: Equilibrium control

"Equilibrium control" is a control of the plasma current, position, and shape, where the poloidal field (PF) coils (including the central solenoid (CS)) are used as actuators. From all appearances with a time constant of about 0.1 ms, we can approximate that a microscopic dynamic state of equilibrium always exists at every point in a plasma. In addition to the microscopic equilibrium of the forces in a plasma, the macroscopic plasma motion is an important factor in equilibrium analysis because a magnetic field is formed when magnetic lines of force pass through the conductors, which can induce eddy currents in structures such as the vacuum vessel.

The macroscopic objective of equilibrium control is to control the plasma current and plasma shape.

- (a) Plasma initiation and plasma current control: ppw commands for the Center Solenoid voltage is sent to a power supply, and its output is applied as a one-turn voltage for plasma start-up, and subsequently, the plasma current ramp-up rapidly. Feedback control is applied according to the given ppw of plasma current after a few tens of milliseconds from plasma initiation until the discharge ends.
- (b) Plasma shape and position control: Feedback control is performed in accordance with the predetermined position and shape of the commanded input ppw. A detached plasma, so called the divertor configuration is achieved accordingly in this series of plasma shape and position control.

The equilibrium control in the JT-60U was a typical feedback control on a basis of proportional-derivative (PD) control, in which the control signal was generated in proportional to the deviations between the target ppw of plasma current, position, and shape and the measured values. PD gain matrices are used so that a multivariable linear feedback control method can be applied.

By controlling the plasma current profile precisely during start-up, it is well known that a plasma current profile with central hollow current, can be obtained. This is so called negative magnetic shear configuration, where an internal transport barrier (ITBs) is formed in the plasma leading to a high plasma confinement performance. Using this method, a fusion energy gain factor of 1.25 (when converted for the DT-equivalent plasma) was achieved in the JT-60U. Thus, the advancement of plasma equilibrium control is a key to achieving and maintaining high performance plasmas. And hence, now a days, it has been established that the plasma shape and position, and equilibrium parameters are precisely reproduced in real-time by the method actually employed in the experiment ([Kurihara, 2000](#)).

Comparatively slow control of plasma

"Density control" is one of the three indicators of plasma performance, and high plasma density is required to achieve high performance plasmas. The method for controlling plasma density is to manipulate the amount of fuel (deuterium and tritium) injection by gas or cryogenic pellets into the main plasma and apply feedback control so that the average values of plasma electron density match the expected waveform. The fuel injection can be achieved rather quickly in the order of less than seconds. However, the gas pumping and wall saturation requires longer time scale of up to minutes to hours. The density control together with particle exhaust including helium ash is a future issue to be tackled in long pulse operations of magnetic confinement fusion machines.

The "fusion reaction rate control" corresponds to power control in a fusion device. The power of the heating systems, such as neutral beam injectors (NBI), is adjusted and feedback control is applied so the increased neutron generation rate, caused by the increase in plasma ion temperature, matches the expected waveform.

As previously mentioned, the plasma heating by alpha particles in fusion reactors is high (70% in ITER and 90% in prototype reactors such as DEMO). This will require rather meticulous and maybe non-linear control, since the pressure profile, which determines the fusion power profile (and hence the fusion power profile equal to the alpha-heating profile), is itself dependent on the alpha-heating profile.

In steady-state reactors, plasma current must be driven in a steady-state manner without using electric fields that are induced by poloidal field coils or Center Solenoid. Thus, non-inductive current drive is achieved by electron cyclotron heating (ECH), ion cyclotron heating (ICH), and N-NBI (negative ion based neutral beam injectors), which act as the actuators. In the negative magnetic shear regime, the direct external current drive is to be reduced by increasing the fraction of bootstrap current, that is, to drive additional bootstrap current in the plasma by creating a large pressure gradient in the plasma. This will again require sophisticated control against non-linear variation of plasma current.

Investment protection system (IPS)

Tokamak machines built recently, such as JT-60SA and ITER, are large investment with superconducting magnets, powerful heating systems capable of operating long pulses. So the control system of such machines equip investment protection functions.

In ITER as an example, the Investment Protection System is provided in the control system, which is largely implemented in a separate, more "robust" hardware and software framework than PCS. But even PCS is utilized for the investment protection: The PCS detects whether the plasma has strayed too far from the planned operating regime and so the PCS decides to implement a controlled shutdown (which might avoid a later disruption). These actions can also be considered as an element of the investment protection system, through "defense in depth." In ITER the IPS is primarily implemented through the Central Interlock System (CIS). CIS also triggers the Disruption Mitigation System, though most of the triggering decisions are made by PCS.

It should be noted here that neither PCS nor CIS are formally part of the “safety” protection system, except in the sense that it is the first step in the “defense in depth” philosophy which is an element of the overall safety framework.

Safety protection system

Safety Protection System in ITER, so called Central Safety System, (CSS), applies exclusively to personnel, population, and environmental safety. This uses even more robust and simpler and independent hardware and software systems than PCS and CIS.

In relation to the plasma shutdown requirement at abnormal events, the safety control system could be structured as:

(i) Controlled slow or fast equilibrium shutdown via PCS;

In the case of an abnormal event in a plant, the power injection systems, such as the heating systems, are stopped and the plasma current is shutdown immediately by using an equilibrium control system. In case of failures in control systems, coils, power supplies, or plasma anomalies, if plasma position and shape control is functional, the plasma is controlled so that it does not come into contact with the wall and the energy of the plasma is gradually discharged by resistive heating or radiation outflow from a plasma.

(ii) Fast plasma termination via “disruption mitigation system (DMS),”

In tokamak plasmas, “disruptions,” the sudden termination of a plasma due to a rapidly growing instability, must be taken into account. Comparatively slow disruptions require plasma current control to be performed for as long as possible to match the decreasing plasma current and recover as much of the plasma’s magnetic energy as possible. In particular, coil current must be controlled at acceptable levels so as not to exceed PF coils allowable stress.

Sudden disruptions rapidly change the position and shape of the plasma, which can induce currents in in-vessel components, generate large magnetic forces on the structures surrounding the plasma, and dump a lot of heat on the vessel wall, all at the same time. Disruptions must be avoided at all costs, but nevertheless must be planned for should an abnormality occur. For fast disruption, ITER CSS can directly intervene to shutdown the plasma to satisfy *safety* requirements (essentially using a very simple approach to “disruption mitigation”).

A disruption mitigation system (DMS in ITER) is mediated by the plasma control, but physically triggered by the interlock control, as it is essentially an investment protection measure. One could also note that in a reactor, this is essential, but that the plasma operation should be organized so that this needs to be used very rarely.

The development of disruption avoidance control and mitigation systems is paramount. Research is already underway on applications of artificial intelligence (AI) and real-time processing of instability prediction. A system that can catch the signatures of disruptions and release the energy in the plasma via radiative process by injecting impurities such as D, He, Ar, thus preventing the in-vessel components from being damaged, is also in development.

Introduction

The aim of controlled fusion is to produce electricity from the energy released by fusion reactions with a competitive cost efficiency, maximum safety and with least environmental impact. In order for nuclear reactions to become effective, the fusion particles of relevant energies in keV range must be brought together at sufficient concentration for sufficient time defined by Lawson criterion (Lawson, 1957), as discussed in detail in Wade (2021). The Lawson criterion defines the condition, at which the energy balance is positive by comparing the energy released in fusion reactions to the energy lost to the environment. Quantitatively, for deuterium (D) and tritium (T) reaction, assuming 50%–50% mixture and temperature above 10 keV (1.16×10^8 K), the Lawson criterion can be written as:

$$n\tau_E > 10^{20} \text{ s} \times \text{m}^{-3}, \quad (1)$$

where n is the number density of reacting particles and τ_E is the energy confinement time. From the formula (1) we may see that there are two possible ways to attain the positive balance of energy gained from fusion compared to energy losses:

1. by increasing the confinement time at the given density of reacting particles;
or
2. by increasing the density of reacting particles possibly, interacting within the very short time.

These fundamentally different approaches have led to two main technological concepts in realizing the controlled production of nuclear fusion energy: magnetic confinement concept and inertial confinement concept.

In magnetic confinement fusion (MCF) devices, such as tokamaks (Artsimovich, 1972; Wesson and Campbell, 2011), described in detail by Zohm (2021) and stellarators (Spitzer et al., 1954), discussed by Yamada (2021) and relatively rarely, magnetic traps (Ioffe, 1965). The long-pulse or quasi-stationary fusion plasmas are confined in the vacuum vessel by a strong magnetic field. In tokamaks and stellarators, such a magnetic field is created using the external coils surrounding a donut-shaped vacuum vessel. The variety of magnetic configurations is discussed in detail by Galvao (2021).

Inertial fusion (IFE) relies on the exposure of deuterium—tritium targets, implosively compressed and heated by intensive laser or ion beams. In the IFE devices, plasma is free to expand after the implosion of the D-T target. More details on inertial fusion concepts and underlying physics can be found e.g. in [Atzeni \(2021\)](#).

In both concepts, MCF and IFE, fluxes of fusion plasma particles and intensive radiation come into contact with materials of fusion device. Depending on their function, several material classes are used in the components of the fusion facility illustrated schematically in [Fig. 1](#):

Plasma-facing materials. These materials are exposed to plasma particle and radiation fluxes directly. The role of these materials is to protect the inner structure of the fusion device and to guarantee the low level of plasma impurities in the plasma.

Blanket materials. These materials are located behind the plasma-facing materials. Their main role is to ensure tritium breeding needed for “refilling” the fusion plasma with tritium and to conduct the heat generated by the products of fusion reaction to the coolant—in order to produce electricity from it later.

Diagnostic materials. These materials are used for multiple measurement (i.e. diagnostic) systems of a fusion device. The main role of diagnostic materials is to transfer the information: electromagnetic radiation (e.g. light) from the main fusion plasma towards the corresponding detectors and sensors.

Materials for magnets. These materials are used in the main field magnets and in various magnetic subsystems needed for plasma confinement, positioning and stabilization and for distribution of plasma loads.

Structural materials. The role of these materials is to support the entire first wall, blanket, diagnostic infrastructure and magnets in the most robust and reliable manner. Structural materials are also used to provide the required vacuum conditions in the fusion facility. These materials have to preserve the entire infrastructure integrity under challenging pressure, temperature and seismological conditions.

Magnetic confinement fusion devices

Edge plasma and scrape-off layer

In magnetic confinement fusion devices, in most of the volume occupied by the plasma, the trajectories of plasma particles never intersect the wall of plasma vessel, creating the so-called confined plasma volume, as illustrated in [Fig. 2](#). The total plasma thermal energy accumulated in the central, core confined plasma in a modern tokamak such as ITER ([ITER Fusion Reactor Website, 2020](#)) can be as high as several hundreds of megajoules (MJ) ([Shimada et al., 2007](#)), whereas in a fusion power plant thermal energy is

Fig. 2 Main areas occupied by fusion plasmas in a magnetic fusion device: a cross-section of JET tokamak with outlined scrape-off layer (SOL) in between the main confined plasma and the first wall. Adapted from Costley AE (2019) Towards a compact spherical tokamak fusion pilot plant. *Philosophical Transactions of the Royal Society A: Mathematical, Physical and Engineering Sciences* 377(2141). doi: 10.1098/rsta.2017.0439.

expected to be of order of one gigajoule (GJ) (Federici et al., 2017, 2018). To confine large accumulated energy, magnetic fields with strengths of several Tesla are used in modern magnetic confinement fusion devices. However, complete confinement cannot be achieved even with the most modern magnet technology.

Due to processes such as collisions between particles and turbulence, heat and particles are transported outwards across the separatrix. In the narrow region outside the confined volume towards the wall, the plasma particles and the heat get in contact with the wall. This happens in the thin, so-called “Scrape-off layer, SOL” between the confined plasma and the vessel wall (Stangeby, 2000) as shown in Fig. 2 adapted from Costley (2019). Particles which cross the separatrix onto the open magnetic field lines in the narrow, typically < 1 cm, SOL can then be transported rapidly to the divertor. A smaller fraction diffuses further outwards and these particles are intercepted by the first wall.

Stationary and transient power loads

The plasma energy in the SOL despite effective magnetic confinement, is nevertheless high enough to cause severe damage to the materials facing the plasma. The most severe stationary power loads are expected to occur in the divertor of magnetic fusion devices at the so-called target plates shown in Fig. 2. There the highest heat loads of the order of $10\text{--}20 \text{ MW} \times \text{m}^{-2}$, are expected in steady-state (Federici et al., 2001; Loarte et al., 2007; Pitts et al., 2011).

Moreover, instabilities in the plasma can lead to significant pulses of heat and particles being ejected into the SOL. In tokamaks, severe adverse effects may be caused by the so-called Edge-Localized Modes or ELMs (Hill, 1997; Stangeby, 2000) formed during the high confinement regime or H-mode (Wagner et al., 1982) and reviewed in greater detail in Zohm (2021) and in Jenko (2021). ELMs originate from plasma instabilities and eject the energy from the central confined plasma, shown in Fig. 2, towards the wall components (Stangeby, 2000). Edge-Localized Modes are capable of delivering several megajoules of energy within milliseconds to the wall components (Hill, 1997; Stangeby, 2000; Loarte, 2006) which can lead to localized melting and ablation of plasma facing surfaces at the divertor targets (Federici et al., 2017, 2018). Significant research activities have been implemented to establish means for either controlling the ELM frequency and amplitude, e.g. (Rapp et al., 2002; Baylor et al., 2012; Evans, 2013; Lang et al., 2013) or suppressing them completely, as described e.g. in (Evans, 2013; Loarte et al., 2015; Suttrop et al., 2018). ELM suppression is seen as a crucial aspect of designing plasma scenarios for a fusion reactor.

In addition to ELMs, tokamak disruptions can cause severe divertor thermal loads. Disruptions are global instabilities which can release the entire plasma stored energy on millisecond timescales, resulting in surface heat loads approaching $1 \text{ GW} \times \text{m}^{-2}$. Extensive research is underway to predict, avoid, and mitigate disruptions in tokamaks (Hollmann et al., 2011; Lehnen et al., 2015).

Both the quasi-stationary power loads and transient power loads must be controlled carefully to ensure reliable operation of the plasma and to limit heating and erosion of the plasma facing surfaces thereby ensuring an acceptable lifetime for these surfaces.

The impinging plasma particles and intensive radiation from the plasma trigger complex plasma-material interactions (PMI) which will be described in detail later in the article. In the course of this explanation, we will review the particular impact of these processes on materials and describe the material concepts in use in present-day magnetic confinement fusion devices. Furthermore, we will describe solutions currently foreseen for the next generation of fusion devices and challenges to be addressed on the way to building a fusion power plant. We will review all material classes of magnetic fusion devices in this article. Due to the versatility of plasma-material interaction processes, their complexity and their crucial impact on the lifetime of fusion reactor, the plasma-facing materials will be discussed in greater detail.

Material challenge in magnetic confinement devices

Plasma-facing materials

Plasma—Material interaction processes

Plasma-material interaction (PMI) plays a crucial role in the choice of candidate materials suitable for the environment of fusion facilities. Among the most important are the following PMI processes:

- Sputtering of the wall materials by plasma particles
- Re-deposition of sputtered material, dust formation and transport
- Thermal loads to the plasma-facing components which can cause material melting
- Accumulation of radioactive tritium from the fusion plasma particles in the wall materials and its possible transport inside the materials of a fusion reactor
- Surface modifications and microstructure changes caused by the plasma particles and radiation

The main PMI processes see e.g. (Kirschner et al., 2016) are schematically shown in Fig. 3 (Kirschner, 2020) for the examples of beryllium (Be), molybdenum (Mo) and tungsten (W).

Physical sputtering

Electrons and ions in the core confined plasmas have energies of order of several keV. In the scrape-off layer plasmas, both electron and ion energies decrease significantly. Electrons, due to their low mass, cannot cause sputtering of material. In some cases the residual energy of plasma ions can exceed the threshold energy needed for sputtering of the wall material. The physical sputtering coefficient in the binary collision approximation depends on the masses of impinging and target particles as shown in the pre-factor for energy transfer:

$$\gamma = 4 m_t m_p / (m_t + m_p)^2 \quad (2)$$

where m_t and m_p are the masses of the target material and the projectile respectively (Eckstein et al., 1993). Therefore, the most efficient sputtering occurs in the case of interaction of impinging and target particles of similar masses. Data on sputtering coefficients for most fusion materials can be found e.g. in Eckstein et al. (1993). The sputtering process leads to the reduction of the thickness of the plasma-facing material (PFM), which may adversely affect the lifetime of the entire component. The lifetime estimates for beryllium plates in the ITER fusion reactor (ITER Fusion Reactor Website, 2020), e.g. predict a surface recession of order of 0.01 mm for each plasma discharge due to sputtering (Borodin et al., 2011, 2019). Physical sputtering is frequently followed by processes of re-deposition of sputtered material and its subsequent re-erosion, leading to the stepwise process of so-called material migration in the fusion device.

The ejection of sputtered atoms into the edge plasma leads to core plasma contamination causing an adverse impact on plasma performance (Gruber et al., 2009; Mayer et al., 2009; Neu et al., 2009; Philipps et al., 2010; Tsitrone et al., 2011). Whereas sputtering increases with decreasing target mass, the plasma contamination impact increases super-linearly with increasing mass of the ejected atoms. Therefore, either low mass, i.e. minimized plasma impact or high mass i.e. minimized sputtering rate PFMs are preferred.

Fig. 3 Main processes of plasma-material interaction. Kirschner A (2020) PWI processes. Private communications.

Chemical erosion

The main plasma particles and the wall materials may possess a chemical affinity to each other and thereby undergo chemical reactions and build chemical compounds. The wall material will be then “consumed” in forming these compounds i.e. it will be eroded by chemically active particles. The corresponding process is called chemical erosion. The detailed description of chemical erosion can be found e.g. in Roth (2005). One of the most pronounced examples of plasma-facing materials prone to chemical erosion is carbon. Deuterium and tritium ions and atoms from the plasma interacting with carbon wall readily produce a variety of volatile hydrocarbons (Haasz et al., 1987; Pospieszczyk et al., 1999; Philipps et al., 2003; Roth et al., 2004; Jacob, 2005; Brooks et al., 2014). The hydrocarbons formed are then transported into the plasma and further to plasma-remote areas, such as e.g. pumping ducts. Chemical erosion processes are temperature-activated and their resultant erosion rate can even exceed that of physical sputtering. This happens e.g. in cases when the energies of impinging ions are still below the threshold for sputtering, whereas the temperature of the material and surrounding environment is already sufficient for chemical reactions to occur (Von Keudell and Jacob, 1996; Bohmeyer et al., 2005; Rudakov et al., 2007; Litnovsky et al., 2008; Wong et al., 2013).

Chemical reactivity is, strictly speaking, not necessarily an adverse effect in fusion plasmas. For instance, the chemical affinity of beryllium (Be) to oxygen—a common impurity in fusion plasmas—is effectively used in the JET tokamak to bind the oxygen to the beryllium walls thus forming an extremely stable and hard melting beryllium oxide, removing the oxygen from the plasma and thus purifying the edge plasma.

Fuel retention

Besides the material loss via chemical erosion, compounds formed may contain the plasma fuel particles: deuterium and tritium. Fuel accumulation represents a severe issue, since radioactive tritium e.g. in the form of volatile tritiated carbon compound, may travel long distances in the vacuum vessel until it finally reaches remote areas. Cleaning and conditioning of these remote areas are frequently challenging or even impossible. With time, such material transport and fuel co-deposition will lead to the undesirable accumulation of the radioactive fuel in the reactor (Dittmar et al., 2011; Litnovsky et al., 2011b; Koivuranta et al., 2013; Pégourié et al., 2013). Besides the radioactivity issue, transport of tritium to remote areas contributes to the loss of this costly element, which is indispensable for sustaining fusion reactions.

Some materials, like tungsten, have a low efficiency of tritium accumulation. Here, another issue may arise though. Once implanted into the material, tritium may start to diffuse deeper into the bulk and eventually penetrate into the coolant of the corresponding cooling systems. Increased chemical reactivity leading to a rapid degradation of the performance of cooling material in the tritium-containing environment is a known effect (Hayashi et al., 2006).

Fuel retention, accumulation and transport impose therefore, a significant concern. A set of measures is foreseen in order to minimize the tritium-driven effects. Certainly, a minimal affinity to tritium is desired from the plasma-facing materials and hence, low tritium retention. It is also known that increased temperatures lead to the prompt desorption of accumulated hydrogenic atoms (Roth et al., 2012; Atsumi et al., 1985; Brezinsek et al., 2013; Ryabtsev et al., 2016; Maier et al., 2019; Zlobinski et al., 2019). It will therefore be desirable to keep the operational temperature of the plasma-facing materials at the level of several hundreds of degrees centigrade. As an example, the first wall temperature of the future DEMO fusion power plant is expected to be in the range 600°C–730°C (Igitkhanov et al., 2013). Once tritium has penetrated into the bulk of plasma-facing materials, its transport can be stopped at the interface to the underlying structural material. For this purpose, so-called permeation barriers (Livshits et al., 1990; Levchuk et al., 2004, 2007; Pisarev et al., 2006; Nemanič, 2019; Houben et al., 2020) are being designed. The permeation barriers act, in a sense as a filter for tritium, preventing it from entering the structural material.

Recrystallization and melting

The heat loads on the PFMs can lead to temperatures significantly exceeding melting temperatures of corresponding materials. Plasma-facing materials in the divertor are at most risk. Melting in the divertor area has been extensively studied both experimentally (Coenen et al., 2011, 2015; Matthews et al., 2016; Krieger et al., 2018) and by modeling (Bazylev et al., 2011, 2014). However, accidental melting in the main chamber has also been reported (Matthews et al., 2016). A photograph of a re-solidified melted fragment from the inner wall limiter in JET is presented in Fig. 4. In tokamaks, severe adverse effects may be caused by the ELMs and disruptions described above.

Melt damage is dangerous in itself. After melting, the damaged area often solidifies in a shape which protrudes towards the plasma and intensifies melting and splashing of molten material during the subsequent plasma operation. Such behavior was observed in melting experiments reported both in divertor (Coenen et al., 2015, 2017; Matthews et al., 2016; Krieger et al., 2018) and limiter tokamaks (Sergienko et al., 2007; Bazylev et al., 2011; Coenen et al., 2011). The molten layer experiences current flowing through it. Being located in a magnetic field, the motion of the molten layer is dominated by the $\mathbf{J} \times \mathbf{B}$ force which, depending on geometry, may even exceed the gravity force (Sergienko et al., 2007; Coenen et al., 2011; Matthews et al., 2016). The molten layer of e.g. heavy tungsten may exhibit an unusual property of moving upwards, depending on location of the molten surface.

Resistance to thermal loads and the corresponding avoidance of surface damage and melting is not solely a function of specific material choice, but also of material geometry. Shaping of plasma-facing components becomes necessary for fusion devices. Here, experience from dedicated studies in MCF devices (Litnovsky et al., 2005b, 2011b; Tanabe et al., 2005; Wong et al., 2007; Krieger et al., 2007; Litnovsky et al. 2007a,b, 2009; Rudakov et al., 2009b; Ding et al., 2014; Hong et al., 2014) coupled with modeling (Dejarnac and Gunn, 2007; Komm et al., 2011; Matveev et al., 2014), can be harnessed for construction of the advanced shapes

Fig. 4 A photograph of a re-solidified area of a beryllium plasma-facing component in the JET tokamak following a melting event. Matthews GF, et al. (2016) Melt damage to the JET ITER-like wall and divertor. *Physica Scripta* T167: 14070. doi: 10.1088/0031-8949/t167/1/014070.

required for future plasma-facing components (Litnovsky et al., 2007b; Pitts et al., 2011, 2019; Stangeby, 2011; Hirai et al., 2016). An example of shaping of the tungsten plasma-facing components in the ITER divertor is provided in Fig. 5.

Dust formation and transport

Co-deposition of sputtered material with the fusion fuel, sometimes followed by prompt re-erosion of freshly deposited layers, their further re-deposition and hence, the further transport of the material frequently leads to the formation of thick deposits. Adhesion of those deposits to the surface is usually rather poor, which leads to their flaking. Flakes or larger fragments of material are usually called dust. The dimensions of dust particles varies greatly, from several tens of nanometers to several millimeters. Hence the effects caused by dust are rather diverse: dust may be fairly harmless, disappearing in the remote areas of the machine and sometimes, not even being noticed and, in the other extreme, dust can cause severe plasma contamination, finally leading to radiative collapse and to a plasma disruption and quench (Winter, 1998, 2004; Krasheninnikov et al., 2005, 2008; Rudakov et al., 2009a; Rubel et al., 2018).

The effects of dust were extensively investigated using various diagnostic techniques (Smirnov et al., 2009; Bergsaker et al., 2011; Kantor et al., 2013; Litnovsky et al., 2013; Shalpegin et al., 2015; Tolas et al., 2016). Dedicated studies show that the fraction of dust mobilized from wall surfaces into the plasma is rather small and not exceeding 20% of the entire amount of dust (Litnovsky et al., 2013). Most dust particles travel to the pump ducts or become stuck in hidden areas and gaps of the first wall and divertor. At the same time, dust mobilized into the edge plasma may travel distances as large as several meters in the plasma volume before they are ablated (Krasheninnikov et al., 2005, 2008; Smirnov et al., 2007; Litnovsky et al., 2013; Lazzaro et al., 2020). Dust entering the core plasma volume is rather rare and its effect usually vanishes after several milliseconds of plasma discharge (Rudakov et al., 2009a; Litnovsky et al., 2013). If dust does enter the core plasma, its ablation will provide a massive source of impurities which causes

Fig. 5 Shaped plasma-facing components of the tungsten divertor of ITER. Hirai T, et al. (2016) Use of tungsten material for the ITER divertor. *Nuclear Materials and Energy* 9: 616–622. doi: 10.1016/j.nme.2016.07.003.

unacceptable radiative losses and eventually, leads to plasma collapse due to the loss of density control. The amount of allowed impurities in the core plasma is negligible. For instance the allowable amount of tungsten estimated for a core plasma of ITER is limited to some 0.001% of the main fuel particles (Pütterich et al., 2010). The detected re-mobilization of dust particles increases the residence time of dust in plasmas and degrades the plasma performance further (Ratynskaia et al., 2013; Tolias et al., 2016).

Besides the issues of radiation and plasma control impact, dust may impose a radioactivity hazard by the accumulation and transport of tritium to remote areas. Furthermore, because of its small size, great particle number and hence, large total reaction area, under some conditions dust may pose an explosion hazard, as reviewed in e.g. Grisolia et al. (2009) and may introduce safety hazards during off-normal events that mobilize the in-vessel inventories (Sharpe et al., 2002, 2005; Petti et al., 2006; Skinner et al., 2008). Dust handling represents a cornerstone element in licensing of future fusion facilities (Van Dorselaere et al., 2012; Perrault, 2016; Wu et al., 2016).

Surface and structure modifications, blistering and fuzz formation

Interaction with plasma particles leads to a series of changes both in microstructure and on the surface of plasma-facing materials (Ueda et al., 2014). Corresponding investigations are underway both in the MCF devices (Bernard et al., 2015; Tokitani et al., 2017) and laboratory facilities (Baldwin and Doerner, 2008). Dedicated modeling (Krasheninnikov, 2011; Martynenko and Nagel', 2012; Trufanov et al. 2015) is used to address these changes and to reveal the underlying physics mechanisms.

Plasma-material interaction may lead to e.g. formation of bubbles and blisters (Shu et al., 2007a,b; Miyamoto et al., 2009; Kajita et al., 2011; Yamagiwa et al., 2011; Juslin and Wirth, 2013; Ueda et al., 2014), needle-like structures, sometimes called whiskers (Chih et al., 2011; Doerner et al., 2014; Kreter et al., 2014) and the more complicated structures, called fuzz, see e.g. Ueda et al. (2014). The formation of blisters and fuzz are among the most widespread effects and presently attract the most attention. Blisters are cavities created by implanted and diffused plasma particles: H, D, T and He accumulated beneath the surface of metals. Blisters are therefore filled with a gas. The size of blisters varies depending on environmental conditions, ranging from several nanometers up to several hundreds of micrometers. Depending on conditions, blisters can either grow or break leading to the gas release and, more importantly, trigger crack formation (Hong et al., 2014). Numerous studies (Shu et al. 2007a,b; Miyamoto et al., 2009; Hong et al., 2014; Ueda et al., 2014) were conducted showing that blister evolution is very sensitive to the elemental composition of impinging particles (Shu et al., 2007b; Ueda et al., 2014), their energy (Buzi et al., 2014), structure of plasma-facing material (Manhard et al., 2017), the temperature of the material (Ueda et al., 2014) and its crystal orientation (Shu et al., 2007a). A concise physics understanding and evaluation of blister formation are still to be attained.

Fuzz formation is another effect triggered by plasma-material interaction. Under specific conditions of high flux and correspondingly, high fluence of helium ions, and at surface temperatures in the range of several hundred degrees centigrade, the formation of the thin, nanometer-sized and long (hundreds of nanometer in length) column-like structures—"fuzz" is routinely observed (Baldwin and Doerner, 2008; Kajita et al., 2009; Gasparyan et al., 2016). Fuzz is usually formed on the surface of heavy metal plasma-facing materials, like tungsten. Unlike blisters with clearly detrimental effect on consistency and mechanical properties of the exposed material, there is no consistent opinion on the role of the fuzz in plasma-material interaction. On one hand, the surfaces with fuzz are expected to be vulnerable to heat loads (Ueda et al., 2011; Brezinsek et al., 2017b). On the other hand, modeling studies e.g. Krasheninnikov (2011) predict the fuzz in fact, to be more stable than the solid substrate material to the sputtering due to relatively small partial area of the fuzz, which can be hit by plasma particles and become sputtered without a prompt re-deposition to the neighboring fuzz structure. As in the case for blisters, the formation of fuzz is highly dependent on environmental conditions in a fusion device. Presently, it is assumed that the growth of fuzz is dependent on competing erosion of fuzz structure and its annealing due to transient heat loads (De Temmerman et al., 2019). The formation of deposits covering fuzz was detected on the tungsten surface of a material test-sample in the divertor of ASDEX Upgrade (Brezinsek et al., 2017b), whereas the pre-grown fuzz placed in the outer SOL plasmas of TEXTOR vanished within a few plasma discharges (Ueda et al., 2011).

Plasma-facing materials: Material choice

The processes of plasma-material interactions discussed above represent a severe challenge for candidate materials needed for the next generation of MCF devices like ITER and further, for a fusion power plant. The optimum plasma facing material should simultaneously possess several, in part contradictory, properties in order to be compatible with the harsh fusion environment. The most important, almost compulsory, properties include:

- Low tritium retention
- Low sputtering yield by plasma particles
- High thermal conductivity at elevated temperatures above 200°C
- As low as possible neutron-induced radioactivity in fusion environment
- Wherever possible, low chemical activity
- Wherever possible, ability to capture or bind plasma impurities

Here we briefly review past, current and prospective candidate materials and concepts.

Carbon and carbon composites

For several decades, carbon (Merola et al., 2004) was one of the most widespread PFMs for fusion devices (Barabash et al., 1999; Duffy, 2009). Its extraordinary properties, such as absence of melting, very high thermal conductivity, even further enhanced in the so-called carbon fiber composites (Snead and Ferraris, 2020), low brittleness and hence, easy machinability are some of the most attractive features of carbon. However, carbon is prone to chemical erosion of carbon (Mech et al., 1998; Philipps et al., 2003; Roth, 2005) described above. Volatile hydrocarbons can travel long distances. Since radioactive tritium reacts with carbon, the so-called long range transport (Wienhold et al., 1999, 2003; Matthews, 2005) can lead to tritium accumulation in poorly accessible areas of the fusion reactor. Being a light element, carbon is prone to physical sputtering by plasma particles (Eckstein et al., 1993). These properties and their implications for reactor operation, have ultimately disqualified carbon as a prospective fusion material (Neu et al., 2009; Pitts et al., 2011; Hong et al., 2015).

Beryllium

Beryllium (Be) has received significant interest as a plasma-facing material within the fusion community, in particular in existing fusion experiments such as JET. Beryllium, still being a light element with rather high physical sputtering vulnerability (Eckstein et al., 1993), features greatly suppressed chemical erosion when compared with that of carbon (De Temmerman et al., 2008; Carpentier et al., 2011). At the same time, beryllium possesses an excellent capability to binding oxygen (Winter, 1996; Tomastik et al., 2005; Konings et al., 2012; Wauters et al., 2020)—a highly deleterious impurity for fusion plasma performance responsible for undesirable radiative cooling of the plasma (Breton et al., 1976; Rogerson et al., 1977; Morozov et al., 2007) and for the enhanced sputtering of plasma-facing materials. Beryllium is therefore, the candidate material for the first wall of fusion devices where particle, thermal and neutron loads are rather benign.

The application of beryllium in a fusion power plant would be however, impossible. As a light material, Be would be subject to intolerable sputtering and material losses during a quasi-stationary operation. A fusion power plant will feature extremely high neutron fluence as compared to that of any present MCF device including ITER. In the course of neutron irradiation, Be will be a subject to transmutation leading to the formation of primarily ^{10}Be , ^7Li , and ^6Li (M R Gilbert and Sublet, 2016), as well as significant gas formation, particularly from helium ^4He , ^3He which could cause embrittlement problems (Martin and Ellis, 1963; Gelles et al., 1994; Kesternich and Ullmaier, 2003; Gilbert et al., 2012).

Tungsten

Achievements in plasma position control (Cenedese and Sartori, 2004; De Tommasi, 2019), well-developed scenarios for auxiliary heating (Gruber et al., 2009) have returned heavy metal options as future plasma-facing materials (Mayer et al., 2009; Neu et al., 2009; Brezinsek et al., 2017a; Pitts et al., 2019) into consideration. Tungsten (W) with its excellent thermal conductivity, low sputtering yield with respect to light plasma particles, highest melting temperature among non-ceramic materials, low tritium retention and moderate activation by fusion neutrons is deemed presently to be the best choice for plasma-loaded areas, like the divertor (Loarte et al., 2007; Pitts et al., 2011).

A material mix: Be for the first wall and W in the divertor, has been successfully used for plasma-facing materials in JET (Matthews et al., 2007; Philipps et al., 2010). In recent years, tungsten was successfully applied as a PFM in large MCF devices: besides JET, tungsten is used in ASDEX Upgrade (Neu et al., 2009) for the entire coverage of the first wall and divertor as well as in WEST (Missirlian et al., 2014; Firdaouss et al., 2017). There are also plans to make a tungsten divertor in JT 60SA. After the successful attempt with tungsten in LHD (Tokitani et al., 2019), this material is currently under the consideration for the future divertor in the Wendelstein 7-X advanced stellarator in Germany.

There are also disadvantageous properties of tungsten. Fusion plasma is highly sensitive to tungsten as an impurity (Pütterich et al., 2010), since this material radiates very effectively leading to undesirable radiative loss of fusion energy in the core plasma. Melting of tungsten may impose the issue, especially during transient events (Coenen et al., 2011; Matthews et al., 2016; Krieger et al., 2018) or re-attachment of the divertor plasma (Bonnin et al., 2017; Eldon et al., 2017). Recrystallization of tungsten in the course of thermal excursions (Guo et al., 2018; Morgan et al., 2020) may change its mechanical properties and affect the exploitation of the plasma-facing components. Tungsten exhibits an extensive crack network developed under repetitive heat loads (Klimov et al., 2011; Herrmann et al., 2017; Zammuto et al., 2018), which may lead to thermal fatigue failure. Tungsten oxidizes readily at elevated temperatures and the oxide of tungsten is volatile. At room temperature, pure tungsten is a very brittle material and its machining is a challenging task. Under these circumstances, the use of pure tungsten in a future fusion power plant is deemed to be problematic. New, advanced materials are being created, significantly expanding the functionality of pure tungsten as needed for the power plant application.

Advanced plasma facing materials

We have reviewed the current challenges in selecting a suitable plasma-facing material for the construction of near-future fusion experiments. For the next ultimate step—the fusion power plant, PFM challenges will increase significantly. Whereas the plasma parameters are not expected to differ greatly from those expected in the ITER experiment, the key difference is much higher particle and especially, neutron fluence. The severe neutron environment will bring new effects adversely affecting material performance. Another significant challenge will be to maintain the thermo-mechanical functionality of plasma-facing materials throughout the entire service life of the power plant. This may lead, possibly, to an avoidance of specific plasma scenarios. A third significant

challenge is due to significantly increased safety requirements imposed on a quasi-stationary power plant. The costs and availability of the source materials and technological feasibility of the component manufacturing are important factors, too. The analyses of new aspects influencing the fusion materials (Maisonnier, 2005; Coenen et al., 2016; Federici et al., 2017; Wenninger et al., 2017; Coenen, 2020) have outlined the necessity of the advanced material concepts. Advanced materials possess unique features, significantly extending the properties of conventional materials in critical areas of their functionality. The development of advanced materials has been focused on four main directions:

- Doped tungsten
- Tungsten composites
- Binary solid solution alloys
- Multi-component alloys

An extensive summary of the mentioned concepts is provided in e.g. Rieth et al. (2019). Usually, advanced material is being developed using a combination of element selection and advanced technology thus representing the material concept. We will briefly review a few mostly advanced material concepts.

Intrinsic properties of tungsten, such as its brittleness at room and elevated temperature were improved using cold rolling combined with thin plate preparation technology, applied successfully for the production of tungsten laminates (Reiser et al., 2017). The remarkable feature of these laminates is their engineered ductility even at room temperature.

Tungsten fiber composites or W_f/W , have been introduced in order to extend the applicability and robustness of tungsten, especially during cyclic high heat loads (Riesch et al., 2014; Jasper et al., 2016; Coenen et al., 2018). Millimeter-size tungsten fibers with a diameter of about 150 microns are introduced into a tungsten matrix (Jasper et al., 2015; Coenen et al., 2018; Mao et al., 2018, 2019a,b, 2020). Fibers are coated with an interface layer of erbia Er_2O_3 or yttria Y_2O_3 having a typical thickness of several microns, ensuring a weak interface between the fiber and the matrix. The main idea behind the tungsten fiber materials is in the dissipation of energy, which otherwise would feed into the buildup of stresses, crack propagation and finally, to the destruction of the component. The W_f/W features an unique pseudo-ductility and therefore, is much more resilient against damage than monolithic tungsten (Coenen et al., 2018; Mao et al., 2020). Another promising concept is the so-called microstructured W, where an array of millimeter-size tungsten tubes with diameter of $\sim 150 \mu m$ is directly integrated into the heat sink material. Microstructured W has already demonstrated impressive results by surviving extreme repetitive high heat loads expected in the divertor area (Terra et al., 2019) without a damage.

Significant progress was attained in production of tungsten components using the so-called power-injection molding (PIM). In this process, the tungsten powder is fed into a cavity where it is pressed into the desired form using high pressure. The significant advantages of PIM is the speed of the process and the ability to obtain components of practically any shape and geometry (Antusch et al., 2011).

Another promising concept, self-passivating (Koch and Bolt, 2007; Koch et al., 2009, 2011), so-called “smart” tungsten-based alloys (López-Ruiz et al., 2011; García-Rosales et al., 2014; Litnovsky et al., 2017a,c,d) has been proposed for the first wall of the future fusion power plant. During regular operation, smart alloys should exhibit advantages of a pure tungsten plasma-facing surface. During an accident, the alloying elements in the bulk form a protective layer and prevent the sublimation of neutron-activated tungsten oxide into the atmosphere. Modern tungsten-chromium yttrium smart alloys feature at least 10^4 -fold suppression of oxidation (Wegener et al., 2016, 2017; Litnovsky 2017c; Klein et al., 2018a) and more than a 40-fold reduction of sublimation (Klein et al., 2018b). Photographs of smart alloys and pure tungsten before and after exposure under accident conditions are shown in Fig. 6. Plasma tests (Litnovsky et al., 2017d; Schmitz et al., 2018, 2019) confirmed a similar sputtering resistance of smart alloys and tungsten to deuterium plasma under conditions expected at the first wall of a fusion power plant (Litnovsky et al., 2020; Schmitz, 2020).

New alloys with a controlled microstructure were developed for application in a high neutron flux environment feature reduced recrystallization and high tensile strength under extreme conditions (Kurishita et al., 2010; Nogami et al., 2020). This promising concept of so-called nano-engineered alloys was pursued in (Zhang et al., 2017). The small nanometer-size chromium inclusions are formed between the tungsten grains in tungsten-chromium and tungsten-chromium-titanium alloys. The formation of nano-size chromium-rich phase effectively opposes recrystallization and grain coarsening under neutron irradiation and temperature excursions.

Studying the effects caused by neutron irradiation are a vital part of the testing and qualification of materials for a future fusion power plant. In particular, the damage produced by neutrons and corresponding transmutation is a focus of these investigations. Several approaches exist to study in particular, the neutron damage, such as e.g. ion self-damage see e.g. Markelj et al. (2013) and exposure to fission neutrons. However, comprehensive testing under fusion relevant conditions is only possible with a fusion-relevant neutron source (Gilbert and Sublet, 2017). The International Fusion Materials Irradiation Facility—DEMO Oriented Neutron Source (IFMIF-DONES) is the major facility presently under construction to address the effects caused by fusion neutrons on materials (IFMIF DONES Facility, 2020). The IFMIF-DONES facility is reviewed in Donne et al. (2021).

Liquid metals

Liquid metals represent another, unique class of plasma-facing materials under investigation. Unlike the solid metals described above, where extreme care was taken to preserve the initial surface and microstructure, in the concept of the liquid first wall these

Fig. 6 Photographs of a pure tungsten sample and a tungsten-based smart alloy exposed under accident conditions as expected in DEMO power plant: (A) tungsten sample before exposure; (B) oxidized tungsten sample after exposure; (C) smart alloy sample before exposure and (D) smart alloy sample after exposure.

properties are discarded from the beginning. Instead, a constant renewal of the liquid metal surface is the fundamental feature of liquid metal application (Nygren and Tabarés, 2016; Ruzic et al., 2017; Zakharov, 2019), thus mitigating the issues mentioned, such as erosion and surface and transient damage. Many approaches to realize the liquid metal first wall have been investigated, ranging from a free molten surface (Ono et al., 2017; Yang et al., 2017) to a rather sophisticated, but the most promising, self-sustaining surface realized via a capillary porous structure, CPS (Evtikhin et al., 2002b; Khripunov et al., 2003; Mirnov et al., 2006; Lyublinsky et al., 2007; Coenen et al., 2014). In the CPS, the stability and the adherence of the metal molten layer is maintained by the capillary forces acting on the metal melt that soaks through the supporting metal mesh of submillimeter size. Several candidate materials are presently under investigations (Mazzitelli et al., 2011), such as lithium (Lyublinsky et al., 2007) and tin (Lyublinski et al., 2016; Roccella et al., 2020). Lithium is among the most promising materials, due to its low melting temperature, low Z number and the possibility of using it as tritium breeder in the fusion power plant (Evtikhin et al., 2002a; Nagayama, 2009). Laboratory studies have demonstrated the superior ability of a lithium liquid surface to withstand the high heat loads exceeding 20 MW/m^2 (Khripunov et al., 2001) by evaporating and creating a dense and cold lithium plasma in front of the liquid metal surface (Khripunov et al., 2001). It was shown that most of the power dissipation is realized through the vaporization of lithium. Successful realization of prototype first wall components have been reported from present day devices (Mirnov et al., 2006; Mazzitelli et al., 2011; Ono et al., 2017), where liquid metal structures, mostly CPS, were installed both in the divertor area (Ono et al., 2017) and as a part of the first wall. Among the challenges imposed by realization of the liquid metal solution are the recycling of lithium and re-liquidation of the molten layers and the collection and re-feeding of lithium to the first wall structures. An important issue is the transport of the vapor created by plasma-material interaction and the re-solidification of lithium in remote, usually cold and hardly accessible parts of the MCF device, causing metal contamination of the sensitive, mostly optical, diagnostic components (Khripunov et al., 2001). Uptake of deuterium and tritium via lithium layers, prompt creation of lithium hydrides and their subsequent transport to the distant areas and, potentially, into the inner structures of the device represent a critical issue for the application of liquid metals as PFMs for a fusion power plant (Ono et al., 2017). Intensive R&D efforts are currently underway to address the mentioned issues and several proposals for the first wall and divertor components of the power plant have been created and are proceeding towards realization (Evtikhin et al., 2002a; Nagayama, 2009; Morgan et al., 2018).

Blanket materials

In a fusion power plant, the plasma-facing first wall and the breeding blanket will constitute a common structure. The purpose of the blanket is the breeding of tritium needed for the tritium self-sufficiency of the fusion power plant as reviewed in detail by L.V. Boccaccini in (Boccaccini, 2021). The blanket must, in addition, play a major role in transferring the heat to the heat exchangers and finally, in converting the heat to electricity. The blanket structure is, therefore, crucial for the success of the controlled nuclear fusion concept (Stork et al., 2014a,b; Stieglitz et al., 2018; Federici et al., 2019). Depending on the blanket construction, a dedicated neutron multiplier may be used. Alternatively, the breeding material of the blanket itself will be used as a neutron multiplier. Presently, there are several blanket concepts under the development. These concepts can be divided into three main types:

- liquid metal concepts;
- ceramic breeder concepts;
and recently proposed
- concepts based on molten salt, is considered in the end of this section

In the liquid metal concepts, either pure lithium or lead-lithium eutectic alloy (PbLi) is used. There are two essentially different design solutions for the liquid metal blankets. In the single-coolant design, the liquid metal will be used both for breeding and for cooling of the blanket structure, whereas in the dual-coolant concept, liquid metal is used for breeding only and a separate coolant, water or helium, is used for cooling.

Among the most developed liquid metal breeder concepts are:

- Water-cooled lead-lithium blanket (WCLL)
- Helium-cooled lead-lithium blanket (HCLL)
and
- Dual-cooled lead-lithium blanket (DCLL)

In the solid breeding blanket concepts, a solid medium in the form of ceramic pebbles or spheres is enclosed in the body of the beryllium neutron multiplier. Among the known and most developed concepts are:

- Helium-cooled ceramic blanket (HCPB)
- Helium-cooled ceramic breeder graphite collector (HCCR)
- Water-cooled ceramic breeder (WCCB)

Blanket construction is rather complex, comprising the cooling, tritium extraction, coolant purification and instrumentation systems and control subsystems. The principal blanket concepts are presented and assessed in e.g. Giancarli et al. (2012), and Abdou et al. (2015). It is planned to test the major breeding blanket concepts: HCLL, WCCB and HCCR, in ITER environment using the so-called test blanket modules (Boccaccini et al., 2004; Giancarli et al., 2012; Boccaccini, 2013; Abdou et al., 2015; Zmitko et al., 2017). In ITER, however, the tritium breeding efficiency and effective heat production cannot be tested due to insufficient neutron fluxes (Giancarli et al., 2012; Abdou et al., 2015) at the ITER first wall. Nevertheless, the entire construction of the blanket can be evaluated, including the consistent functioning of all essential subsystems and the results can be used for further extrapolative modeling (Giancarli et al., 2012). There are several proposals for the future full functional test of the breeder solutions, including the building of a dedicated Fusion Science Nuclear Facility, as proposed by the United States.

Operation of the breeding blanket is accompanied with several, in part crucial, issues and risks. Among those, the interaction of a slowly moving conductive liquid metal with a strong magnetic field, which causes significant Lorentz forces. In several concepts, such as DCLL and HCLL, insulating so-called flow channel inserts (FCIs) are foreseen in order to minimize these conductive circuits and hence, to limit the electromagnetic forces acting on the blanket. The structure of the blanket is expected to be made from magnetic steel. The use of magnetic material leads to stresses in the construction and may distort the magnetic field configuration in the power plant, especially during the ramp-up and ramp-down phases of plasma operation (Zmitko et al., 2017). Finally, general safety and tritium isolation impose severe requirements on tritium permeation, efficient evacuation and containment. In general, the following requirements are specified for blanket materials:

- Neutron robustness, reduced activation
- Tritium opacity
- Reduction of electromagnetic forces
- Thermo-mechanical stability of the entire construction

Generally, the principle of Reliability/Availability/Maintainability/Inspectability (RAMI) (Abdou et al., 2015) is applied to the entire blanket construction. The application of RAMI to materials used in blanket construction has led to the material selection described below. There are three classes of functional blanket materials: the structural materials, the materials for flow channel inserts and the tritium permeation barrier (TPBs) materials.

For the structural blanket materials, reduced activation ferritic-martensitic steels (RAFM) are selected. In the European HCLL and HCPB concepts, the use of Eurofer (Van der Schaaf et al., 2003; Möslang et al., 2005; Boccaccini, 2013; Tassone et al., 2018) is foreseen, whereas in the WCCB concept proposed by Japan, the F82H RAFM steel is planned as a structural material (Giancarli et al., 2012; Tanigawa et al., 2017). Significant R&D activity is underway in order to assess, among others, the interaction

of helium coolant with RAFM as well as the complex interaction with the PbLi (Flament et al., 1992; Tortorelli, 1992; Malang and Mattas, 1995; Moreau et al., 2011; Abdou et al., 2015; Zmitko et al., 2017).

For flowing channel insulation the main candidate solution is silicon carbide (SiC). The use of SiC for FCIs, in bulk or in dense foam form brings several advantages, such as significant reduction of the MHD loads and a rise of operation temperature to about 700°C. Such a high operation temperature however, exceeds the current temperature window of the RAFM application (Möslang et al., 2005; Abdou et al., 2015; Tanigawa et al., 2017; Tassone et al., 2018). In addition, the high temperature response of SiC to neutron irradiation, as well as technological concerns of manufacturing the complex geometries of FCIs out of SiC, need further exploration. The potential interaction of FCIs with the e.g. PbLi eutectic and RAFM are among potential concerns (Pint et al., 2007; Muroga, 2012; Abdou et al., 2015; Smolentsev et al., 2015). The use of alumina (Al_2O_3) as an alternative to SiC is still under assessment. Here, the radiation hardness and activation properties are among major concerns (Abdou et al., 2015).

Tritium permeation barriers have to be implemented within the blanket structure. Their role in the breeding blanket becomes even more important, since the TPBs must warrant efficient containment, and refill the bred tritium to the power plant, including the reservoir systems to be used in case of blanket failure (Abdou et al., 2015). Permeation barriers under development (Livshits et al., 1990; Levchuk et al., 2004, 2007; Pisarev et al., 2006; Houben et al., 2020) are already providing an efficient tritium isolation. Modern barriers made of yttria (Houben et al., 2020) may provide more than a 10^6 -fold decrease of tritium flux permeation to the bulk of the facility in the temperature range of 300°C–600°C (Houben et al., 2020).

In the blanket environment, the reactions with liquid breeder and coolant, as well as possible interactions with structural materials and FCIs, must be investigated. Performance studies of neutron-irradiated TPBs are of crucial importance for the breeder blanket.

As mentioned above, the interaction of the working fluid or solid breeder and neutron-multiplier materials with the functional elements of the blanket, is important. The chemical and mechanical durability of breeder and multiplier materials themselves represents a crucial topic for the blanket feasibility. We will not provide a comprehensive overview of all issues and open questions in the section, but mention a few. The use of beryllium as neutron multiplier in e.g. ceramic breeders faces issues due to the radiation-induced volumetric swelling, reaching 16% at 650°C (Abdou et al., 2015; Fedorov et al., 2016). The use of the beryllium intermetallic phase Be_{12}Ti seems advantageous in this respect. However, water-beryllium interaction in the case of liquid blankets imposes problems (Abdou et al., 2015). For the dual-coolant systems, such as DCCL, the permeation of bred tritium into the helium-coolant circuit is considered as critical, imposing stringent requirements for TPBs.

In relation to the molten salt concepts noted above, the main potential advantage of using e.g. F-Li-Be or F-Li-Na-Be salts is their low electrical conductivity. This would alleviate the MHD issues of the conductive medium. Molten salts are also relatively chemically inert. At the same time, their high viscosity and high melting point limit the operating window severely. In addition, under neutron irradiation, the corrosive interaction of molten salts with the interior of the blanket, leading to the potential release of highly active and toxic fluorine, represents a significant concern.

Diagnostic materials

Another class of materials in MCF devices which are at least partly exposed to plasma particles are the materials of diagnostic components. Here, the difference between the present-day devices and the coming experiments, e.g. ITER, is rather distinct. The particle, neutron and radiation environment in present-day devices is rather benign and the plasma pulses are usually limited to several seconds. A wide range of materials can be used without any significant risk or degradation of performance or with relatively easy exchange possibilities. On the contrary, in the devices of ITER-class, the neutron and radiation fluxes are orders of magnitude larger (Costley et al., 2001, 2005; Walker et al., 2005; Donné et al., 2007) than those in any of the present MCF devices, and hence cannot be neglected. In the following description, we will focus on diagnostic material challenge for fusion devices of the ITER-class and for the fusion power plant.

Due to the harsh neutron environment, the use of refractive optical elements i.e. lenses and prisms, will be impossible in these MCF devices, mostly due to the inability of the corresponding materials to withstand neutron irradiation (Voitsenya et al., 2001; Voitsenya and Litnovsky, 2009). A reflective, mirror-based option will be used instead. Diagnostic mirrors will guide the plasma radiation towards spectrometers and detectors (Costley et al., 2001; Donné et al., 2007; Litnovsky et al., 2019a). The first optical element directly viewing the plasma is the so-called first mirror. It is one of the most important diagnostic elements overall, given the number and importance of optical diagnostics and the fact that the performance of the entire corresponding diagnostic largely relies on the performance of its first mirror and hence, on the mirror material. Moreover, it will become necessary to clean the mirrors from the deposited material eroded from the first wall and the divertor—these processes are described earlier in the subchapter “Plasma-material interaction processes”. The repetitive cleaning will be performed in situ using a local plasma for sputtering the impurities from the mirror surface (Litnovsky et al., 2011a, 2015, 2019b; Mukhin et al., 2012; Moser et al., 2015; Leipold et al., 2016; Peng et al., 2018; Yan et al., 2018). Single crystal mirrors made from highly reflective materials, such as molybdenum and rhodium are among the main candidates for the diagnostic mirrors (Voitsenya et al., 2001; Litnovsky et al., 2005a, 2007c, 2017b, 2019b; Matveeva et al., 2010; Peng et al., 2018). Mirrors coated with a reflective molybdenum or rhodium layer are under investigation (Marot et al., 2007; Eren et al., 2011). As for the further, more distant, secondary mirrors, the environmental conditions are not as restrictive and therefore the choice of materials increases. Currently, stainless steel and aluminum mirrors coated with protective sapphire or tantalum oxide Ta_2O_5 layers are being considered (Mukhin et al., 2008a). Alternatively, secondary mirrors with titanium dioxide and silica highly reflective layered coating oxide are under study (Krimmer et al., 2013); however, attaining the desired long-term performance is challenging.

For some diagnostics (Mukhin et al., 2008b, 2009), protective windows are foreseen. Windows will be used as well as vacuum isolation for several diagnostics. Fused silica, sapphire and quartz are presently the main candidate window materials (Aymar, 2002). As for duct and corresponding support structures, most diagnostics are expected to use steel (Kalinin et al., 2000; Voitsenya et al., 2001; Krasikov et al., 2011). For fusion power plants, the choice will most probably be made in favor of reduced-activation steels due to the increased neutron irradiation. These steels are described in detail in the next section.

Material choice for the other elements of the reflective optical paths, such as fiber bundles, appears to be challenging. A range of neutron-induced changes or effects, such as radiation-induced electromotive effect, radiation-induced conductivity, radiation-induced electric degradation and generally, non-ohmic behavior, may affect the performance and degrade the lifetime of the fiber materials (Zinkle, 1994; Aymar, 2002). Current studies show advantages from using mineral insulated cables (Vayakis et al., 2008). However, care must still be taken to avoid radiation-induced effects (Vila and Hodgson, 2009), depending on their chemical and elemental purity of the fiber material (Hodgson, 1998). Similar issues with radiation-induced effects will be experienced by the other diagnostic components such as e.g. imaging bolometers (Peterson et al., 2008).

In a fusion power plant, the requirements for diagnostic materials and assemblies will likely be even more demanding. Only a few crucial optical diagnostics will remain, and mirrors should be of reduced size and placed far away from the plasma (Orsitto et al., 2016; Biel et al., 2019). In addition, reserve optical channels should be foreseen to ensure continued operation in case of the failure of the main diagnostic (Litnovsky et al., 2010; Biel et al., 2019).

Structural materials

The main function of structural materials in current plasma devices is in providing the mechanical support to components, as well as defining the vacuum vessel boundary. Furthermore, the structural components contain the cooling infrastructure of MCF devices and ensure the required vacuum conditions. The functionality of structural materials in current fusion machines and hence, their choice, depends largely on interface properties to PFMs, blanket materials and chemical resistance to the reactive, humid or corrosive environment (Lässer et al., 2007; Zinkle and Busby, 2009). Presently, austenitic stainless steel of different types is the most widespread structural material (Kalinin et al., 2000; Barabash et al., 2007). In ITER, most of the supporting structures will be made of type 316L stainless steel (Kalinin et al., 2000). The heat sink interface material to the water-cooling infrastructure will be provided by a high strength, high conductivity copper alloy (CuCrZr) (Kalinin et al., 2000; Barabash et al., 2007).

Requirements for structural materials increase significantly in a fusion power plant due to the long required lifetimes at high temperatures in the presence of high fluxes of energetic neutrons, corrosive fluids, and large cyclic thermomechanical stresses. Superior mechanical properties and resistance to radiation induced property degradation such as embrittlement and void swelling are required to ensure acceptable reliability and component lifetimes before replacement, and low residual activation following prolonged exposure to energetic neutrons is required for safety and recycling/waste disposal considerations (Bloom, 1998). Key properties include superior elevated temperature thermo-mechanical creep-fatigue properties, resistance to neutron-induced embrittlement and stress corrosion cracking, resistance to radiation-induced dimensional changes due to irradiation creep or void swelling, and high temperature coolant corrosion resistance (Bloom et al., 2007). A particularly daunting challenge is the high levels of transmutant hydrogen (H) and helium (He) that are produced in most materials by the 14 MeV neutrons generated in the deuterium-tritium fusion reaction. These H and He gaseous transmutants tend to enhance radiation degradation processes such as low temperature embrittlement, intermediate temperature void swelling, and high temperature grain boundary embrittlement (Dai et al., 2012; Zinkle et al., 2019) dramatically. Due to the worldwide lack of a suitably intense prototypic 14 MeV neutron source (Zinkle and Möslang, 2013; Knaster et al., 2016), estimates of potential degradation rates are mainly based on limited simulation experiments and computational modeling predictions. Therefore, the structural material suite being considered for fusion power plants is quite broad.

Reduced activation ferritic-martensitic (RAFM) steels developed for fusion are the current leading candidates. These include Eurofer (Lindau et al., 2005; Möslang et al., 2005), Rusfer (Chernov et al., 2010; Rogozhkin et al., 2012; Tyumentsev et al., 2012), CLAM (Huang, 2014), F82H (Jitsukawa et al., 2002; Tanigawa et al., 2011) and JLF-1 (Kohyama et al., 1998). The historic evolution of the RAFM steel development and current status is provided e.g. in Kohyama et al. (1996); Tanigawa et al. (2017). The favorable reduced activation properties of RAFM steels is largely due to replacement of undesirable solute elements (Mo, Nb) in commercial high performance steels with similar-functioning reduced-activity elements (W, V, Ta) (Klueh and Bloom, 1985; M.R. Gilbert and Sublet, 2016). A wide variety of ultra-high-performance alternatives to the baseline RAFM steels are under intense investigation, due to concerns that higher performance properties and/or radiation resistance may be needed for next step fusion energy devices (Lindau et al., 2005; Klueh et al., 2007; Zinkle et al., 2017). These high performance alternative steels generally utilize ultra-high densities of nanoscale particles such as oxides, carbides or nitrides to improve high temperature strength and neutron radiation resistance.

Promising risk mitigation alternatives to RAFM structural materials under investigation include silicon carbide ceramic composites (Snead et al., 2007; Katoh et al., 2014) and refractory alloys such as V-4Cr-4Ti (Zinkle, 2005; Zinkle et al., 2013; Muroga et al., 2014). These structural materials offer the potential for improved thermodynamic efficiency due to $\sim 200^{\circ}\text{C}$ – 400°C higher operating range than that of RAFM steels, along with potentially improved radiation resistance compared to RAFM steels. However, the industrial experience with these materials is much less compared to that for steel production and use in engineering systems.

For the use of low-activation steels, good interface to the PFMs plays a crucial role. Due to significant difference in a wide variety of crucial parameters and, primarily, thermal conductivity and thermal expansion coefficients, direct joining of tungsten to low-activation steel is challenging (Driemeyer et al., 1999; Bachurina et al., 2018). Various joining techniques are under study, including

brazing (de Prado et al., 2017; Bachurina et al., 2018), hot isostatic pressing (Driemeyer et al., 1999), field-assisted sintering technology, creation of functionally graded materials (Weber et al., 2013; Heuer et al., 2020); the use of tungsten laminates (Reiser et al., 2017) and additive manufacturing look promising. Here, the strength of the interface, the inter-diffusion of steel elements and tungsten, the phase formation and the durability under cyclic heat loads are the prime criteria for feasibility.

Tritium safety must be applied to the structural materials. The development of tritium barriers reviewed earlier in the article must suppress the undesirable diffusion of tritium in the bulk materials and prevent tritium interaction with the coolant.

Structural materials must also provide an efficient and robust interface to the cooling structure. Here, depending on coolant type, various materials or alloys with a high thermal conductivity are under investigation. For water-cooled high heat flux structural applications, the most promising are high-strength, high conductivity Cu alloys such as CuCrZr (Pintsuk et al., 2010; Barabash et al., 2011; Stork et al., 2014a; You, 2015; Richou et al., 2017, 2020) and other Cu alloys or composites are under development (You, 2015; Zinkle, 2016; Wang et al., 2020).

Different joining methods are under development (Nicholas et al., 2018) for providing robust interfaces to the heat sink materials. Joints initially created by hot isostatic pressing (HIP) face challenges, mainly due to severe thermal expansion mismatch of tungsten and heat sink materials (Barabash et al., 2000; Rigal et al., 2000). Recently, melt infiltration (Muller et al., 2017) and field-assisted sintering technology (FAST) (Galatanu et al., 2017, 2019) were applied successfully. Direct joining of tungsten to the heat sink material is another strategy of interest for divertor applications, etc. Additive manufacturing as a technique for direct joining of tungsten and the heat sink material is also under consideration (Müller et al., 2019).

Materials for magnets

Despite years of research, the magnet systems in fusion reactors are still considered to be one of the primary life-limiting components. Difficulties associated with replacing, in particular, toroidal field coils are considered a barrier to commercialization of fusion (Chislett-Mcdonald et al., 2019). The current material of choice as the superconducting material for EU-DEMO applications is niobium (Nb)—tin (Sn) alloy Nb₃Sn, but long-term reliability is an issue because of its brittleness. Nb-Ti, which is commonly used in magnetic resonance imaging machines, is a potential ductile alternative, which was recently proven applicable for advanced fusion systems with well-controlled plasma confinement requiring lower magnetic fields (Chislett-Mcdonald et al., 2019).

Meanwhile, “High temperature” (20–40 K) Rare-Earth-Ba-Cu-O (REBCO) superconducting tapes are being explored for conventional (Heller et al., 2015) and compact (spherical) fusion devices because of their ability to carry more current at higher field compared to conventional low temperature (4 K) superconductors, which is critical for compact devices (Sorbom et al., 2016; Sykes et al., 2018). These materials are immature and inherently brittle and understanding of how such materials withstand neutron irradiation damage is still largely missing. Since no ductile solution for high-field superconductors has so far been found, there is active research in devising economic engineering solutions to the problem of replacing field coils made from REBCO or otherwise (Tsui et al., 2016), which could also benefit the lower temperature options. Demountable joints are an attractive solution, allowing a modular construction of coils and making replacement easier (Sorbom et al., 2016). Soldering of the joints, e.g. using tin-based solders (Tsui et al., 2016) is the most promising solution. However, challenges are still to be overcome concerning the ability of the joints to carry currents and the reliability and repeatability of the joining process that could be required in thousands of locations in a typical fusion reactor system (Sagara et al., 2014).

Materials for inertial fusion devices

Introduction

The development of the facilities for inertial fusion is mainly focused on reaching the prime goal of attaining the ignition of D-T targets. Material development for the inertial fusion facilities is accompanying the mentioned mainstream research. Due to the different operation modes of IFE and MCF facilities, major requirements deviate significantly for these two concepts. At the same time, there are also distinct similarities. Specifically, the similarities can be noticed in requirements for the materials suggested for IFE facilities. Information on material research for IFE facilities is not as abundant as that for MCF devices. Nevertheless, the intensive pilot research conducted provides a sufficient degree of specification of the envisaged material concepts.

A schematic view of the inertial fusion facility is presented in Fig. 7 on the example of the European facility HiPER (HiPER facility website, 2020). Laser beams focused on the frozen D-T target with dimensions of several millimeter will ablate the outer layers of the target compressing it and causing the fusion D-T reaction reviewed in details in (Atzeni, 2021). The reaction volume is contained in a spherical reaction chamber where, as in MCF devices, the first wall will be exposed to the products of a fusion reaction. The spherical reaction chamber is the inner sphere in Fig. 7. The first wall will be fixed to the structural material, providing the mechanical support and acting as a chamber shield. The so-called final optical assembly (FOA) is contained within the second, larger spherical shield. The massive structure will hold optical tubes used to direct the powerful laser radiation beamed through the set of mirrors and lenses to the D-T target. Finally, the external cylindrical wall will encapsulate the entire volume of the inertial fusion facility. Depending on requirements and functionality the suggested materials for an IFE facility will be divided into several different classes:

- a. First wall materials
- b. Structural materials
- c. Optical materials

Fig. 7 A preliminary design of HiPER. Adapted from Ruiz JA, Rivera A, et al. (2011a) Materials research for HiPER laser fusion facilities: Chamber wall, structural material and final optics. *Fusion Science and Technology* 60: 565–569. doi: 10.13182/FST11-A12443.

In this sub-section we will review the main challenges and requirements for these material classes and will survey the candidate materials suggested for IFE.

Material challenges and requirements in IFE

Owing to the nature of the inertial operation, significant heat loads are expected inside the IFE facilities. Presently, the laser systems with a total power ranging from 0.5 to 1.5 megajoules will beam onto the D-T target with very short pulses of one to several nanoseconds (Chanteloup et al., 2010; Sethian et al., 2010; Ruiz et al., 2011a; Colier et al., 2013; Miquel et al., 2016; Norimatsu et al., 2017). The entire IFE facility is expected to operate with a shot frequency of several hertz. The resulting fusion energy of order of tens of megajoules, will be unloaded within the first few hundreds of nanoseconds onto the components of the first wall in the reaction chamber. The massive particle, heat and radiation loads impose a significant challenge for first wall materials. In HiPER, the expected loads to the first materials can reach about 200 GW/m^2 for the He ions originating from fusion reactions. The debris particles originating from the non-ablated remainder of D-T capsule will lead to loads of order of 40 GW/m^2 (Perlado et al., 2012) exposing the first wall for about $2 \mu\text{s}$ with a repetition rate of 1–10 Hz (Ruiz et al., 2011b).

Pulsed operation of the IFE facility will provide an additional complication. The nearly instantaneous release of a large amount of energy will impose the risk of melting and sublimation and splashing of plasma-facing materials (Norimatsu et al., 2010, 2017; Sethian et al., 2010; Ruiz et al., 2011a). Additionally, the cyclic mode of operation with a high repetition rate of shots, 24 h a day and 7 days a week in the timeframe of the envisaged 20–30 years of operation of IFE (Sethian et al., 2010; Ruiz et al., 2011a; Norimatsu et al., 2017) will significantly increase the probability of material failure as a consequence of, e.g. thermal fatigue.

Finally, intensive particle and neutron radiation originating from the D-T reactions will induce the substantial radioactivity in the components of the IFE reactor. The radiological aspects of nuclear fusion facilities are reviewed in the Chapter 01229 by N. Taylor (2021).

Material choice for IFE facilities

Plasma-facing materials

Material choice for the first wall of the reaction chamber varies strongly depending on particular design (Perlado et al., 2010, 2018; Sethian et al., 2010; Norimatsu et al., 2017). The two essential material options under consideration are:

- Solid (dry) wall
- Liquid wall

In some cases, in the course of design development there is a transition between the first wall options: a solid wall to be exchanged for a liquid wall as it was in case for the Japanese laser fusion commercial reactor project KOYO-F (Norimatsu et al., 2017). An additional options to reduce damage of the first wall includes magnetic diversion of fusion-generated ions (Sethian et al., 2010).

The choice of a solid wall usually is justified by the required robustness of the design from the beginning, based largely on the experience obtained at the MCF facilities and corresponding MCF materials testing program. Here, the reader may notice distinct similarities in material choice for IFE and MCF facilities. Because of known problems with tritium retention and formation of volatile hydrocarbons, carbon was eliminated as a candidate material for the first wall armor. Due to its natural advantages mentioned earlier, tungsten is currently being considered as the prime candidate material of the solid first wall (Juarez et al., 2010; Perlado et al., 2010, 2018; Sethian et al., 2010; Ruiz et al., 2011a). Depending on the specific design, the thickness of the first wall varies between 1 mm and 1 cm (Juarez et al., 2010; Perlado et al., 2010, 2018; Sethian et al., 2010). Alternatively, tungsten alloys or nano-structured tungsten are suggested to gain the advantage of reduced recrystallization and to relieve neutron effects (Perlado et al., 2018). It is expected that the use of tungsten with its advantageous properties will relieve the effect of thermal loads on the first wall of the envisaged ICF devices—a similar approach is followed for MCF facilities. At the same time, there is still a risk of tungsten melting, which was predicted for the particular conservative scenario in HiPER (Ruiz et al., 2011a,b). Here, the peak pulse of X-rays created after the reaction pushes the temperature of the W-armor to 3300°C within several microseconds. Detailed calculations reveal an increased risk of temperature excursions of the plasma-closest layers of the armor. Owing to the very fast response to the reaction event, the power load from the fusion burn reaches the first wall within several nanoseconds and after 1 μ s up to 50% of generated power is absorbed within the first 1 μ m of the tungsten wall. More realistic modeling taking into account the time evolution of the heating pulse predicts, fortunately, peak temperatures of around 1530°C (Ruiz et al., 2011a). Another essential issue is tritium permeation through the first wall material. The corresponding research is briefly reported in (Ruiz et al., 2011a). The repetitive heat loads lead to extensive crack formation and cause degradation of the thermo-mechanical properties of tungsten, as well as provoking mechanical fatigue of W (Sethian et al., 2010), as known from the MCF research (Linke et al., 2019). The corresponding studies reported for HiPER in (Ruiz et al., 2011a,b) outline the risk of cracking at the 1.5 μ s after the laser shot in HiPER, when the Von Mises stress of tungsten armor exceeded 3 GPa (Blanchard and Martin, 2005). The evolving cracking can degrade the overall mechanical stability of the tungsten first wall and lead, among other consequences, to dust and debris formation.

Nevertheless, the solid wall option is treated as a relatively robust one and is incorporated in the majority of the first wall concepts. The liquid wall concepts are usually based on lithium and either represent pure Li wall solutions or the lithium-lead (Pb) combination—which is advantageous since it integrates the blanket solutions. An extensive study was reported in (Norimatsu et al., 2010, 2017). The repetitive short-pulse power loads will lead to expected effects including liquid splashing and vaporization and, eventually, ablation. The ablation of a plasma-facing 3- μ m thick layer of the first wall per a single laser power pulse was predicted. The ablated materials then become split and in part strike the first wall and can subsequently re-enter the inner volume of the reaction center. Modeling predictions were experimentally validated. The propagation velocity of the ablated plume of first wall materials is of order of $1 \text{ km} \times \text{s}^{-1}$, as detected using the Mie scattering technique (Norimatsu et al., 2010).

Important information was obtained on the nuclear decay heat in a LiPb first wall. For the LIFT test reactor (Japan) with a nominal projected fusion energy of 40 MJ per pulse operating at 1 Hz repetition rate, the resulting decay heat in the first wall still exceeds 1 MW after 10,000 h (> 1 year) of operation.

Structural materials

Structural materials in IFE facilities will naturally experience, less intense power and radiation loads than the first wall. At the same time, since structural materials support the first wall armor, their long-term durability under cyclic repetitive mechanical loads and eventually, significant temperature excursions, is required. Various types of steels were therefore proposed for different IFE facilities. In the LIFT project (Japan) an F82H martensitic steel structure will hold the liquid first wall of the blanket, whereas the stainless steel SS 316 will encapsulate the cooling channels. Here, the calculations (Norimatsu et al., 2017) show a temperature periodic rise to 1500°C which will potentially endanger the steel supporting structures.

An extensive study on possible structural material options was undertaken for the HiPER project. Among others, the radiology aspects were considered. A comparative analysis of the Eurofer reduced activation steel developed for MCF (Lindau et al., 2005; Möslang et al., 2005) and the commercial SS304L steel has been performed for the standard expected HiPER operation scenarios. The scenarios comprised 100 MJ of neutron yield per shot and up to 100 shots in one burst repeated at 10 Hz, with one burst per month for 20 years. The results showed clearly that the low contact dose rate attained with SS304L reaches $1.5 \times 10^{-5} \text{ Sv} \times \text{h}^{-1}$ in 50 years which is sufficiently low to qualify this relatively inexpensive steel for the HiPER environment. More details on the reported comparative analysis can be found in (Juarez et al., 2010).

Optical materials

By their nature, all projected IFE facilities require an extensive set of optics to guide the laser radiation to the D-T targets. The optical components comprise both the refractory and focusing optics and corresponding waveguides and supporting systems (Sethian et al., 2010). The structure of optical components is presented in Fig. 7 for the example of the HiPER facility (Ruiz et al., 2011b). In the case of optics, the radiation level and the thermomechanical loads dictate the conditions and largely govern the

design of components. In HiPER, the region between the inner spherical reaction chamber and the outer spherical shield, the outer sphere in Fig. 7, is the location of the so-called disposable optics in the Final Optical Assembly (FOA). It is assumed that optical components of the FOA located within Zone 1, Fig. 7 in the course of the operation become either damaged or displaced and must be regularly exchanged. Optical components outside Zone 1 are stationary and are not supposed to be exchanged.

For optical elements in Zone 2, the prime material for the mirrors and focusing lenses is deemed to be a pure (single crystal) silica based on results of investigations summarized in (Juarez et al., 2010; Ruiz et al., 2011b). At the same time, recent calculations briefly reported in (Ruiz et al., 2011b) suggest the necessity of using cooling for at least a part of optical components. Other final optic options include grazing incidence metal mirrors (Sethian et al., 2010), similar to the choice adopted for MCF systems. For the optical tubes, several materials are under consideration including both low-activation and regular SS304L stainless steel.

Summary and outlook

In this article, we summarized the development of fusion reactor materials—one of the key pillars in attaining the ultimate goal of controlled nuclear fusion, the realization of a fusion power plant. For magnetic confinement devices: tokamaks and stellarators, we have seen the variety of processes occurring during the interactions of fusion plasmas with materials. Among them are: physical sputtering and chemical erosion, recrystallization and melting, tritium accumulation, prompt re-deposition of eroded material leading to the dust formation, and significant changes imposed by plasma particles and radiation on the microstructure and surface of plasma-facing materials. The majority of these processes are also expected to occur in inertial confinement devices. The processes of plasma-material interactions have imposed severe requirements on the candidate material concepts. It is interesting to see a kind of “loop” in the development of fusion materials from metals widely spread in fusion facilities in 1970s, to the light, carbon-based materials and beryllium dominant until 2000s and then, a return to the metals nowadays. Advanced plasma control scenarios, and improved plasma heating knowledge have largely contributed to this return to high-Z refractory metals, such as tungsten. However, achievements were scored not on the plasma side only. The development of new material concepts, such as fiber components, suitable as plasma-facing materials, and significantly advanced engineering of components, have contributed to the return of the high-Z metal option, an option which was even hard to imagine for fusion devices before.

Presently, we are witnessing the next, remarkable stage in the development of plasma-facing materials—the creation of the advanced, entirely novel, high-Z material concepts and alloys. Their features are unique: from the capability of handling enormous heat loads without serious damage, to the resistance to cracking and recrystallization and even a capability to adapt the material properties to the environment—an unbelievable set of properties is now in our hands. A liquid first wall and divertor—options that looked like a fantasy before, are now becoming a reality and we see first design solutions for the liquid metal components for a future fusion power plant.

Material development for the inertial fusion facilities is largely harnessing the intensive synergetic research results gained for magnetic confinement fusion devices. As for the first wall of the reaction chamber, two primary concepts are presently under consideration. The so-called “solid” wall is planned to be built either from pure tungsten or from the advanced nano-grain tungsten or tungsten alloys. Alternatively, for several IFE reactor concepts, a self-cooling lithium-based liquid wall has been suggested. Here, issues may arise potentially with the recycling of liquid material and with the stability of a liquid under cyclic high thermal, mechanical and radiation loads. The advantages of a liquid wall are the ability to act as a blanket for tritium breeding and the absence of a requirement for active cooling.

Optical materials for IFE facilities, such as like mirrors, frequency multipliers and focusing lenses will largely rely on established material concepts. Presently, it is planned to use pure silica for all these elements, although adjustments may become necessary for optic components located in final optical assembly.

Optical systems of the MCF facilities will rely on mirror-based reflective optics. Here, the use of unique, highly reflective material concepts, such as single crystal molybdenum and rhodium for diagnostic mirrors—with their unprecedented capability to preserve the reflectivity under plasma sputtering, have opened the way for mirror-based diagnostics which can last for the entire lifetime of future MCF devices. The dedicated facilities for mirror surface recovery, including in situ mirror cleaning and calibration systems, will support the retention of high mirror performance.

Development of efficient and reliable blanket technology represents technological, physics and engineering challenges. Several promising concepts are under development and their simultaneous testing in the ITER test blanket modules is foreseen as a part of the R&D and qualification program.

Last, but not least, exciting progress has been achieved in structural materials. Whereas, conditions in inertial facilities luckily allow the use of conventional martensitic steel, the creation of the entire class of the reduced activation steels including Eurofer, Rusfer, CLAM, F82H—has dramatically changed the R&D and opened the way to their unmatched functionality in magnetic fusion devices.

Of course, as we have seen, the material choice and especially, the realization of the components for a fusion power plant are still far from the final stage. Significant remaining challenges include the suppression and effective control of transient power and particle loads in MCF and IFE facilities and the long-term degradation of materials. The design of MCF power plants will also benefit from the development of ductile, robust superconducting materials, or from the reliable engineering solutions for existing superconducting materials, an issue which will be addressed by ITER operation.

In a fusion power plant, materials will have to withstand, and retain their functionality under a very high fluence of highly energetic 14 MeV neutrons—and neutron-resistant material solutions must still be thoroughly tested in the burning plasma environment. However, with the solid portfolio of advanced materials developed to date, and considering the impressive progress already made on fusion materials, a significant basis exists for the development of the materials required for construction of a fusion power plant and finally, for the production of fusion—based electricity to the grid.

Glossary

Divertor Dedicated structure within the vacuum vessel onto which the highest plasma exhaust heat fluxes are directed and through which unburned fuel, helium produced in fusion reactions and gaseous impurities are extracted, usually by vacuum pumps (the divertor is toroidally symmetric in a tokamak, but has a more complex geometry in a stellarator).

Dual coolant lead lithium (DCLL) Blanket concept based on lead-lithium breeder with steel as structural material; it is cooled both by the breeder itself flowing in a dedicated loop and by an additional helium loop that provides the cooling of the steel structure.

Ductile-to-brittle transition temperature (DBTT) The temperature at which there is a pronounced decrease in a material's ability to absorb force without fracturing.

Full power day (or year) The equivalent of 24 h (or 365 days) of full power operation by a reactor.

Fusion power (FP) The power directly released by the thermonuclear D-T reaction in the plasma (the energy released per single event is 17.6 MeV)

Heating, ventilation and air conditioning (HVAC) In nuclear technology the HVAC system must provide the functions of maintaining ambient conditions within acceptable limits within the nuclear buildings (temperature, humidity, contamination), protecting the staff and equipment against specific risks from inside the buildings (anoxia, explosion, fire) and, outside of the nuclear buildings, monitoring the release of air from the controlled areas in normal operation, and containing the radioactivity released during accidental events.

Helium cooled pebble bed (HCPB) Blanket concept based on solid breeder in form of a pebble bed and cooled by helium.

Magnetohydrodynamics (MHD) As applied in blanket technology, refers to the influence of the electromagnetic forces on liquid metal breeders, arising from the interaction of the confining magnetic field of the reactor with currents induced in the liquid metal as it flows across the magnetic field.

Self-coolant lithium lead (SCLL) Blanket concept based on lead-lithium used both as breeder and coolant. To allow this feature the selected structural material is SiC_f/SiC.

Test blanket module (TBM) A small (volume $\sim 1 \text{ m}^3$) tritium breeding module which will be exposed to the DT neutron flux in the ITER tokamak to test the performance of prototypical tritium breeding blankets for a DEMO fusion power plant.

Tritium breeding ratio (TBR) This represents "the ratio between the number of tritium atoms produced in the reactor and the number of neutrons made available from the thermonuclear reaction".

Water cooled lead lithium (WCLL) Blanket concept based on lead-lithium breeder and cooled by water at fission pressurized water reactor (PWR) coolant conditions.

Introduction

The breeding blanket (BB) is a key sub-system of the D-T fusion power reactor (FPR) with the main functions of removing heat to use for electrical production, and generating tritium that is one of the fuel elements used for sustaining the thermonuclear D-T reaction. The blanket will also fulfill several secondary functions, i.e., neutron shielding, provision of the first wall-plasma interface and containment of radioactive products. To perform all of these functions effectively, the blankets will surround the burning plasma

with a high coverage factor (usually greater than 0.85), representing the largest in-vessel system of the fusion reactor; their coolant and breeder features strongly influence the technologies employed in the plant design for the overall primary heat transfer system (PHTS) and for tritium management within the facility.

This article presents an overview of the principles of the breeding blanket design and of the main related technologies. Although we have tried to keep the description of this system as general as possible and therefore applicable for any type of fusion reactor, the particular design solutions and the quantitative values presented and discussed here refer to recent studies for a demonstration reactor (DEMO) which is currently considered as the next step after ITER. Our present understanding of DEMO is a fusion device based on the tokamak magnetic configuration of about 1–2 GW of fusion power,¹ relatively large dimensions (major radius of 8–9 m), low power density with an average neutron wall load (see section “Heat removal”) not larger than 1–1.5 MW/m² and a plant life time of about 6–7 full power years. We refer to (Federici et al., 2018) for an overview of the general design and performances of this kind of DEMO device that is considered in the European fusion road map for the breeding blanket development. Extension to blanket application to other magnetic configurations (e.g., stellarator) or inertial confinement will be briefly considered in section “Blanket for tokamak and stellarator” and “Blanket for inertial fusion applications”.

Tritium production and extraction

A fusion power reactor consumes about 153 g of T to sustain each GW of installed fusion power in a full power day; this means that for 25 full power years (FPY) a 2-GW power plant requires about 2.8 t of tritium. A comparable quantity of D (about 1.9 t) must also be provided. While D is present in nature and can be extracted with already consolidated technologies (e.g., it is used in fission technology in the CANDU reactors), tritium is rare in nature due to its half-life of 12.3 years. Industrially usable quantities of this radioactive hydrogen isotope can be produced as result of human activity only. At present it has been estimated that about 25 kg of tritium produced by heavy water reactors (mainly in Canada, Korea or Romania) are available for fusion technology applications (Pearson et al., 2018). However, it is not feasible to supply a D-T reactor externally with the required quantities of tritium, and therefore an FPR should be able: (1) to generate itself all the tritium that it will use during its operation; (2) to rely on an initial charge of tritium (estimated to be several kg) to start the plant and sustain the fueling for the first few days to maintain operation until the breeding blanket and its associated Tritium Systems are able to supply the Fuel Cycle with newly-bred tritium; (3) to produce, at the end of the reactor lifetime, a charge of tritium able to support the start-up of new power plants. These three requirements are usually encompassed under the general plant requirement of “tritium self-sufficiency.”

The production of tritium in the blanket exploits the neutrons generated during D-T reactions within the burning plasma. Lithium is central to this process, as its neutron capture reaction results in the production of tritium. Natural lithium is composed of two isotopes ⁶Li and ⁷Li, with an abundance of ⁶Li of about 7.5% (atomic). Both isotopes can generate tritium via neutron capture, but ⁷Li releases an additional neutron that can be used for a further breeding reaction:

The efficiency with which the reactor produces tritium can be quantified by the Tritium Breeding Ratio (TBR); this is commonly defined as “the ratio between the number of T atoms produced in the reactor and the number of neutrons made available from the thermonuclear reactions.” It is clear that self-sufficiency can be reached only with a TBR > 1. Taking into account that only one new neutron is made available by a D-T reaction (that consumes one atom of tritium and one of deuterium), but that not all of these neutrons will react with a lithium atom, this balance can be sustained only if a considerable neutron multiplication is achieved in the blanket to compensate losses. The loss of neutrons is due to the incomplete coverage of the plasma by the blankets, the limited thickness of the blanket layer and the unavoidable parasitic absorption in other blanket elements, such as structural material and other constituent elements in Li-compounds.

Although ⁷Li can contribute to the neutron multiplication function, the reaction cross-section is small and concentrated only in the medium energy spectrum, so that the use of natural lithium for this purpose does not, in general, satisfy the requirements. Only in combination with very low neutron absorbing materials and large blanket thickness would it be possible to obtain a sufficient TBR. A better strategy is to substitute ⁷Li with a more effective neutron multiplier and enrich the fraction of ⁶Li in the lithium used (to 50–90% according to various designs) in order to capture as large a fraction as possible of neutrons in the low energy region of the neutron spectrum, where ⁶Li has the higher cross section. This leads to the use of elements such as Be or Pb in the blanket material composition. These exhibit a more effective (n, 2n) reaction in a broader neutron energy spectrum:

The physical form of lithiated material for tritium production in the blanket provides a first classification of blanket concepts, namely “solid” and “liquid” breeder blankets. The former make use of solid Li compounds like ternary ceramics (e.g., orthosilicate,

¹Fusion power is defined here as the power directly released by the thermonuclear D-T reactions in the plasma (with an energy of 17.6 MeV per single reaction).

metatitanate, metazirconate) or Li-oxide. The ternary ceramic can be adopted up to $\sim 1000^\circ\text{C}$, but somewhat less for the oxide, which exhibits degradation of mechanical properties. Under thermal cycles and neutron irradiation solid breeders suffer from damage and fragmentation; for this reason, a common use of these materials is in form of a pebble beds, to reduce the modification of their basic properties (e.g., effective thermal conductivity of the pebble bed) in case of a further fragmentation and to allow a control of the breeder temperature during the whole lifetime. The thermal conductivity of these solid beds is in any case low; if cooled by surrounding plates or tubes containing the coolant, they can be used only as thin beds of about 1–1.5 cm. There are several criteria for the selection of the solid breeder material, namely high Li density, low activation (for rapid recycling after irradiation), better mechanical and thermal properties, high chemical compatibility with structural materials, less hygroscopicity for easy handling and mature manufacturing processes. None of the candidate materials are ideal, so that compromises among the various properties are required; among the materials mentioned above, the current preferences in the design are for lithium orthosilicate (Li_4SiO_4) produced by a melting-spraying process, lithium metatitanate (Li_2TiO_3) produced by wet-chemistry and sintering (Tsuchiya et al., 2007), or variants such as the KALOS material ($\text{Li}_4\text{SiO}_4 - 30\% \text{Li}_2\text{TiO}_3$) that is the reference in the EU program (Knitter et al., 2013). Be and Be alloys are the natural neutron multiplier choice to complement the solid breeder; they can be used in form of rods, slab or pebbles. A disadvantage of Be is its chemical reactivity with water, causing hydrogen production; at temperatures higher than 600°C this reaction is exothermic and constitutes a serious safety issue if the blanket uses water cooling. At high temperature the mechanical properties are poor and the swelling excessive; this suggests an upper operational limit of about 650°C . However, tritium retention constitutes the major concern: the simultaneous production of He and tritium in the material during the irradiation chain produces an inventory of tritium trapped in the helium bubbles that grows in the material grains. This tritium is difficult to release at the operational temperatures and can accumulate over time, creating safety concerns (Chakin et al., 2020). The recognition of these issues has led to the development of Be intermetallic compound (Nakamichi et al., 2018), such as Be_{12}Ti or Be_{12}V . In particular, titanium beryllide has been proposed as a solution for the present design of the European HCPB Blanket (see section “Blanket architecture”) in the form of hexagonal rods; it reduces the neutron performance slightly, but improves the compatibility with water, increases the operational temperature and allows a rapid release of the tritium. Beryllides are proposed in Japanese, European, Korean and Chinese blanket concepts, also in combination with water cooling.

Liquid breeder blankets use breeders in the form of liquid lithium or lead lithium eutectic (Pb-15.8% at Li, labeled usually as PbLi). Molten salts, such as FLiBe or FLiNaBe, have also been proposed in several concepts. Liquid breeders can be recirculated outside the blanket, carrying tritium to an external processing plant that allows tritium extraction and purification. All these breeders can also be used as a coolant (see later) in advanced blanket configurations. The advantage of liquid breeders is the practically unlimited lifetime, which contributes to long blanket availability; in fact, breeder damage due to creation of impurities or Li burn-up can be compensated in the ex-vessel reprocessing plant. High thermal conductivity, as in liquid metals, enhances heat removal features. Principal disadvantages are chemical reactions with water, air and other materials; this can be a serious safety issue in the case of accidents involving liquid Li, and a moderate risk for PbLi reacting with steam. Corrosion of structural material is an operational issue; usually coating is necessary to mitigate this effect. The dose rate level of the PbLi is high level; at short cooling times (less than 1 month) the dose rate is dominated by the Pb activation products and afterwards by radionuclides generated from the specified impurities, in particular ^{54}Mn . Volatile transmutation products such as ^{210}Po , a strong alpha emitter, are also generated in chain reactions from Pb. Helium, which can form bubbles, is also produced in the Li reactions. Helium should be removed to avoid accumulation in the PbLi loop; otherwise, if it accumulates in the blanket, it can cause local blockage of the flow. A further issue for electrically conducting liquid breeders is the influence of MHD in the flow. This issue is critical when the liquid metals are used as a coolant (see later), but it can also affect the local flow of the breeder and impact important functions such as heat and tritium transport (Bühler and Mistrangelo, 2017).

The tritium extraction process from the breeder is also related to the type of breeder used. In the case of solid breeder blankets, gas purge flow can be used to extract the tritium from the breeder material in blanket; usually an addition of H or D to the carrier gas (e.g., He) is foreseen to facilitate the tritium extraction per isotopic exchange. The resulting composition of the purge flow shows the presence of HT and HTO at low concentrations ($\sim 1 \text{ Pa}$) in the outlet gas flow. HTO can be extracted by cold traps ($< 0^\circ\text{C}$) or reactive molecular sieve beds (RMSB); for HT the extraction can be performed using cryogenic technology at liquid nitrogen temperature (cryogenic molecular sieve bed, CMSB) or using getter beds at room temperature (Cristescu and Draghia, 2020). In general, all the mentioned technologies are “batch processes” in which the individual getters are installed as a pair: one operates in absorption mode treating the purge gas coming from the reactor, while the other is in regeneration, releasing the H isotopes to the fuel cycle. The dimensioning of these getters and the frequency of switching between the two operating modes are critical parameters for maintaining low tritium inventories and high extraction efficiency of the systems. This technology exists and is used in industrial applications; its application in fusion must be optimized in terms of energy consumption, especially if cryogenic technologies are adopted. Some studies have been undertaken to develop continuous extraction processes, e.g., using “membrane reactors” (Demange, 2011).

In the case of liquid breeders, the extraction process is performed outside the vacuum vessel; hence, the liquid has to recirculate in a dedicated external loop where an extraction unit transfers tritium to the fuel cycle. The recirculating loop should be located near the tokamak to reduce the breeding quantities and to be strongly confined and efficiently shielded within the nuclear island to avoid the spread of the highly activated breeder and its transmutation products. If PbLi is used, $\sim 1000 \text{ t}$ of breeder (e.g., in the WCLL presented in section “Blanket architecture”) has to be recirculated outside the reactor core, leading to a replacement of the blanket inventory approximately 10 times per day. Several processes have been proposed for the tritium extraction (Utili et al., 2019), such as Permeation Against Vacuum (PAV), gas stripping in Gas Liquid Contactors (GLC), or direct exposition to vacuum in the

so-called Liquid Vacuum Contactors (LVC). All of these are continuous processes that are installed in a bypass of the recirculating loop. The principal issue is to demonstrate a technology at high specific extraction efficiency so that it is possible to scale it to systems suitable for operation in DEMO conditions. Extraction processes from liquid Li and molten salts for blanket applications are less studied and in general more challenging e.g., (Tebus et al., 1998) or (Fukada et al., 2017).

The fuel cycle

The processes described above concerning tritium production in the blanket and its transport to an external plant for extraction and removal is an integral part of the general architecture of the fuel cycle for the FPR; it constitutes the so called “outer cycle,” to distinguish it from the main part of the plant (“inner cycle”) that is responsible for the function of managing the exhaust gas coming from the plasma chamber, so as to remove helium produced in the D-T reactions, to extract other impurities formed by plasma-wall interactions, to provide the “fueling” for the plasma and to inject plasma enhancement gases (PEG) needed for plasma stability control. Furthermore, the fuel cycle in dedicated systems will recover tritium from the blanket coolant, which accumulates a tritium inventory due to permeation at the high operation temperatures within the blanket. The “outer cycle” supplies the “inner cycle” with the amount of tritium necessary for the FPR operation; in ITER where the “outer cycle” is missing, the “inner cycle” will have to cope only with the externally supplied tritium provided from the long-term storage.

The design of the fuel cycle is guided by several strict requirements: firstly, to reduce as much as possible the tritium inventories in storage, in the tritium plant and in the vacuum vessel. Regulatory limits (such as the no-evacuation criterion) will set upper boundaries for such inventories which then have to be further reduced following the ALARA approach (as low as reasonably achievable). Furthermore, the scale and cost of the plant should be considered and minimized. The key to reaching a suitable operational point is to select architectures and technologies able to reduce as much as possible the cycle time of the associated processes; in addition, a suitable requirement for the TBR² has to be selected to optimize quantities such as the initial storage, but also to minimize the build-up of inventories. The quantification of the required TBR, as well as that for the initial charge of tritium or for the storage of tritium for a new DEMO start-up, is the result of an optimization of the fuel cycle calculations; it depends on the plasma reaction efficiency, the time constant of the fueling processes, the trapping of T in materials, T decay and performance of the blanket extraction systems. Safety requirements will play a large role in prescribing limitations of tritium inventory in the various parts of the reactor (e.g., vacuum vessel, tritium plant, long term storage). From recent assessments performed for the EU DEMO, a blanket TBR performance of 1.05 is specified (Fischer et al., 2020). The minimum required TBR is defined mainly by the amount of tritium sequestered throughout the fuel cycle systems (saturation of structures and materials) and the time needed to reach this quasi steady-state. Plant lifetime estimates of the tritium inventory evolution do clearly show that under the assumption of a constant TBR above the minimum performance, and for reasonable integral availabilities above 30%, there will be net production of tritium over the lifetime (Coleman et al., 2019). This allows the export of tritium to feed the start-up of the next reactor.

It can be shown by simple mass balances that the design driving load on the fuel cycle is given by one performance indicator, the so-called tritium conversion rate, which is defined as the product of the effective tritium burn-up fraction times the fueling efficiency. The D-T injection rate the fuel cycle has to provide is inversely proportional to the tritium conversion rate. Due to losses of the injected fuel from the core and to limited reactivity of the fuel in the core, only a small fraction of the D-T injected into the plasma will burn (1% in ITER, targeted to be higher than 2.5% in DEMO), while the remainder, together with helium and impurities, will be exhausted and sent to the tritium plant for treatment. The plasma D-T reaction is fed by the fueling system that injects cryogenic D-T pellets. The fueling efficiency, which is defined as the ratio of the plasma fueling rate to the fuel injection rate, is limited. This reflects the fact that there are significant matter losses of the injected pellets on their way to the plasma and only part of the ablated pellet mass remains inside the plasma core due to particle transport processes near the plasma edge. For ITER, the achievable fueling efficiencies are unlikely to be higher than 50%.

A direct consequence of the limited tritium conversion rate is the fact that the tritium throughput that the inner fuel cycle has to remove from the plasma chamber is about a factor of 100 higher than the tritium throughput that the outer fuel cycle takes from the blankets; significant increases of plasma performance in this area cannot be expected. A simple scaling of the ITER fuel cycle to FPR dimensions will result in excessive tritium inventories and does not lead to a suitable solution for DEMO in terms of operational complexity, facility size, but especially for the avoidance of prohibitive inventories. Recently an innovative architecture of the fuel cycle has been proposed for the EU DEMO design in (Day et al., 2016) and (Day et al., 2019), see Fig. 1, which is currently considered as the most promising solution to mitigate the inventory issue.

The suggested architecture features three loops and introduces a separation function close to the divertor, which extracts pure fuel and recycles it via a bypass to the tritium plant, the Direct Internal Recycling (DIR). This shortcut re-routes, within a short processing time, the major part of the tritium in the exhaust gas, so that only a minor fraction will have to be routed through the tritium plant, resulting in reduced plant size under nominal operation conditions. This fraction is again distributed in a faster loop with protium

²“Required TBR” defines the tritium production that should be performed in the fusion reactor to enable continuous FPR operation in the tritium self-sufficiency regime. The “required TBR” should be not confused with other values (generally higher values) that are reported in blanket design reports. Usually these latter values refer to calculated performances in neutronic analyses that are affected by data and modelling uncertainties, and use heavy modelling assumptions, e.g., absence of auxiliary systems that require a reduction of blanket coverage. Whether this level of performance can cover the needs of “required TBR” must be carefully checked in the design.

Fig. 1 Schematic of the fuel cycle architecture for a FPR ($Q = H/D/T$, PEG denotes plasma enhancement gas). This picture has been done by the co-author Day C (2020). It is his intellectual property, but it has been already used also for another publication. *Fusion Engineering and Design* 155: 111553.

removal and isotope re-balancing, which produces DT in the specified composition, and sends the remaining gas to an outermost loop for the tritium recovery, which is very similar to the classical outer fuel cycle (Lawless et al., 2017). This last loop also includes the detritiation of tritiated water. From the perspective of the tritium plant, the introduction of the DIR loop with a nominal separation fraction of 80% would leave a load on the DEMO tritium plant which is a factor of four lower than in a once-through architecture. The introduction of DIR decouples the tritium plant operation from the tokamak operation. Any potential improvement in the tritium conversion rate would further improve the fuel cycle efficiency. The DIR concept builds, moreover, on continuous processes, avoiding accumulation of tritium in each process stage. This is also the reason why a second loop (isotope rebalancing and protium removal) has been introduced to establish, in a quasi-steady-state manner, the fuel mixture that is needed to provide, in combination with the DIR return stream, the fuel composition requested from the pellet injectors. This architecture therefore results in significantly reduced D-T cycle times and tritium inventories, as indicated in Fig. 1, and helps to relax the TBR requirement for the same performance in terms of start-up inventory.

The technical realization of DIR (KALPUREX process in Giegerich and Day, 2014) involves metal foil pumps and linear diffusion pumps for primary pumping, thereby replacing the batchwise cryopumps that are used at present in most fusion devices. The metal foil pump is a novel technology for hydrogen separation that allows the extraction of a pure hydrogenic stream from the exhaust gas mixture under the low pressure conditions close to the divertor, i.e., conditions which exclude the use of the classical membrane separation technology (Hanke et al., 2020). It exploits the phenomenon of superpermeation, which enables suprathermal hydrogen particles to permeate through a metal foil with a surface barrier, whereas all other species in practice do not permeate through the foil. Both product streams of the metal foil pump need further vacuum pumping for compression. To meet the requirements of this process step, continuous pumping systems are being developed, which would make the processing time and resulting inventories negligible. A development program of mercury based continuous vacuum pumping solutions is under way (as mercury has practically zero solubility for tritium) using mercury vapor diffusion pumps backed by liquid ring pumps with mercury as the working fluid.

The main function of the exhaust processing sub-system is to separate the arriving gas mixture into three streams, namely (i) the fuel stream for re-use, (ii) the stream of PEGs via appropriately sized decay tanks for the activated species, and (iii) the remaining detritiated impurity stream. For inventory and continuity reasons, classical permeation membrane technology with a number of suitably sized palladium-silver permeators will be employed for bulk hydrogen separation. Also for tritium recovery from tritiated impurities, ITER technologies based on membrane reactors may well serve as a good candidate. For PEG separation there exist several technologies that have to be chosen once the type of PEGs to be used is known: options include cryogenic trapping or molecular sieving by porous membranes (Tosti et al., 2017).

Classically, the central technology in the outermost fuel cycle loop is isotope separation via cryogenic distillation to separate the incoming hydrogenic gas stream into the different pure hydrogen isotopes. Cryogenic distillation suffers from the inventory issue in that there are significant quantities of hydrogen isotopes being liquefied, and this is the main factor responsible for the long processing times assumed for this fuel cycle loop. ITER has established the requirement to provide the different isotopes in pure form, mainly to provide experimental flexibility within the ITER research program. This is not required for DEMO operation, where essentially one and the same plasma discharge will be repeated. It is therefore sufficient to provide mainly D_2 and T_2 at the requested composition (around 1:1). This situation brings back a technology which had been discarded at ITER, because it does not achieve the same purity requirements as cryogenic distillation, but it does have the advantage of shorter processing times. It is embedded in the additional system block which provides the intermediate processing loop prior to the classical isotope separation in Fig. 1. The

task of isotope rebalancing is to re-establish the required fuel mixture composition before reinjection into the torus, while protium removal separates protium, which inevitably enters the fuel cycle via outgassing or replacement reactions. The resultant fuel stream with adjusted mixture composition directly feeds the gas distribution and control box, as does the permeated stream from the metal foil pumps. The operation principle of the intermediate loop is based on membrane-coupled temperature swing absorption (Neugebauer et al., 2020). The main feature is the combination of two separation principles—Isotope dependent gaseous diffusion through porous membranes, and hydrogen-metal interactions by temperature cycling of the gas between two materials, one with a positive isotope effect that absorbs the heavier isotopologues more readily, and the other with an inverse isotope effect which preferentially absorbs the lighter isotopologues. The addition of a membrane acts as pre-separation, thereby reducing the tritium inventory and separation time. The joint unit for the two functions making up the intermediate processing loop consists of two columns. In the first, a flow enriched in tritium will be sent to the gas management system. In the second column all the protium plus a certain amount of deuterium are separated and sent to isotope separation. One advantage of the absorption-based technology is that it provides some flexibility to work at different target points so that the composition of the fuel injected into the tokamak could be adjusted—although slowly.

The discharge of tritium must be minimized in accordance with the ALARA principle and must, at least, remain below the regulatory discharge limits. The exhaust detritiation system is a key component in ensuring that this objective is met, by capturing any tritium, from waste process gas or potentially contaminated air, in both gas and water vapor form. This includes input streams coming from heating, ventilation and air conditioning (HVAC) systems, glove box vent systems and air from other rooms with tritiated components. The tritium is prevented from leaving the facility into the environment and instead will be made available for re-use. As in ITER, it is expected that exhaust detritiation on DEMO will operate on the principle of converting tritium to tritiated water, consequentially, this is the main feed of water into the water detritiation system.

The leading technology choice for water detritiation is combined electrolysis and catalytic exchange (CECE), which is an industrialized process well developed for heavy water detritiation of CANDU reactors (Spagnolo and Miller, 1995). It is believed that the design for DEMO can be derived from that developed for ITER, however at a clearly larger size. Due to the direct electrolysis, the CECE process is very energy intensive, as are alternative technologies at a similar readiness level. A more efficient technology is desirable, and R&D is ongoing in this area, although, at present, at a rather fundamental level (Lozada-Hidalgo et al., 2016).

To complete the overview of the tritium systems connected to the fueling function, we present in the following the tritium recovery from the main coolant. This “purification” technology is essential in the design of DEMO reactors that use water or gas as coolant (see section “Blanket architecture”) where the contamination (mainly due to permeation in the blanket structures) of the PHTS with several % of the tritium produced in the breeder is an issue for the tritium control in the reactor. Obviously, the coolant purification system (CPS) will be first-of-a-kind at the DEMO scale (Santucci et al., 2020). The main functions of the CPS are (i) extraction of tritium from the coolant to below specified levels, (ii) removal of solid, liquid and gaseous impurities, and (iii) control of the coolant chemistry (by adjusting the oxidation-reduction potential of the coolant). The largest challenge comes from the huge coolant flow rate (several 1000 kg/s of water or helium). The general strategy is, therefore, that only a fraction of the coolant flow is processed by the CPS, to be determined by the assumed CPS efficiency, the total coolant flow rate, the tritium permeation rate from the blanket to the coolant loop, and the allowable tritium concentration inside the coolant.

For identification of a promising helium CPS technology, one can start from the CPS of the helium-cooled test blanket modules (TBM) of ITER, in which the tritium removal foresees the transformation of HT into HTO by the use of high temperature oxidizing beds and subsequent adsorption of the resulting tritiated water in molecular sieve beds at room temperature. The process proposed for the ITER CPS uses mature and consolidated technologies (that are also being used in fission applications). In principle such a process can be scaled up to fulfill DEMO requirements, but it comes with some drawbacks and operational complexity. An alternative solution is therefore being explored based on new, high capacity, non-evaporable getter (NEG) materials which would avoid the oxidation step.

For detritiation of the water coolant, one may use the same CECE technology mentioned above. However, the water CPS functions are only manageable if a suitable strategy for reducing T permeation from the blanket into the coolant is applied; initial estimates specify required permeation reduction factors between 100 and 1000. In the latter case, an ITER-sized system would be sufficient to manage the tritium inventory in the coolant loop. Given the importance of permeation barriers, a strong R&D program is currently ongoing world-wide, including demonstration under reactor conditions. The alternative approach for the water CPS would be an off-line plant, assuming that the water coolant in the primary cooling system is replaced with fresh water after 1 year of DEMO operation.

Heat removal

As described more in detail in the thermal load conditions in operation for in-vessel components like the blanket are characterized by three major sources of heat. 80% of the fusion power leaves the plasma in form of neutron kinetic energy. The neutrons then interact with the surrounding materials releasing their energy progressively while attenuating the flux with an exponential law. The plasma source intensity can be quantified locally by the neutron wall load (NWL): NWL is the energy flux transported by the 14 MeV neutrons crossing a reference closed surface surrounding the plasma ring (usually a reference surface that follows the FW contour). In a tokamak this distribution is almost axisymmetric so that the neutron wall load can be described as a function of the poloidal angle. In a stellarator the distribution will depend on the poloidal and toroidal angles as the closed magnetic surfaces

are helical with fully 3D geometry. In the present European DEMO device, the maximum NWL will be around 1 MW/m^2 for a total fusion power of $\sim 2 \text{ GW}$. The heat deposition decays exponentially through the radial blanket thickness, with a peak value in the plasma-facing region not exceeding 20 MW/m^3 .

The remaining 20% of the fusion power associated with the alpha particles, together with the additional power injected by the external heating provided by the H&CD Systems, leaves the plasma either in the form of electromagnetic waves or via plasma thermal conduction and particle convection processes. The electromagnetic waves are emitted mainly via Bremsstrahlung and synchrotron radiation and via impurity line radiation: the radiation will produce a power load of about 0.3 MW/m^2 on the surface of the blankets with peaks at the equatorial plane. The plasma particles (ions and electrons) contributing to conduction and convection follow the magnetic field lines in the scrape-off layer (SOL), moving toroidally and poloidally in the direction of the divertor targets. In the course of this process (which can occur over a field line length of $\sim 100 \text{ m}$ in the case of DEMO) particles can impact tangentially on the blanket surface, producing localized hot spots.

To remove and transport the heat to a power generation plant, a range of materials and corresponding technologies have been proposed for the blanket cooling: water, gases, liquid metals or molten salts. Water has been proposed at the thermo-hydraulic conditions of fission PWRs that foresee a pressure of 15.5 MPa and water temperatures in the range $285\text{--}335^\circ\text{C}$; this specification allows retention of the liquid phase with sufficient margin to critical heat flow. The advantages are excellent cooling characteristics (high density, heat capacity and heat transfer coefficient) that lead to systems with low pumping power and low temperature differences between inlet and outlet. The level of temperature is, however, relatively low, leading to low thermo-hydraulic efficiency of the power generation systems (a minimum of $\sim 33\%$ is desirable) and issues with ferritic-martensitic steels under irradiation (DBTT shifts to room temperatures after $20\text{--}30 \text{ dpa}$, as described in Litnovsky, 2021). An increase in temperature is not possible while maintaining PWR operating conditions; to overcome this limitation supercritical water conditions can be selected, but the performance deteriorates and the issue of compatibility with steels (corrosion) becomes critical. The use of PWR technology ensures the availability of components and equipment (i.e., pumps, steam generators, pressurizers, valves) with high technological readiness level (TRL). In spite of the extensive use of these technologies in fission applications, several issues are still open for their application to fusion technology. In particular the energy of the neutrons is higher than in fission, enhancing water radiolysis and activation, and, in addition, tritium can be trapped in water, increasing its inventory in the coolant if not efficiently removed.

Among the gas coolants, helium is the preferred option; it is chemically compatible to all the other materials in operational and accident conditions and is not modified significantly under exposure to neutron or ionizing radiation. Helium has no intrinsic limitation in temperature range of application, and a high temperature range is favorable to increase the thermo-hydraulic efficiency of the power generation cycles; the limitations are due to the materials that constitute the pressure containment (degeneration of chemical and mechanical properties at very high temperature). As a gas, the cooling capability is less effective than water, since the density is much lower; this increases the resulting volumetric flow and the dimensions of the components of the cooling system. To remove comparable heat power without increasing too much the dimensions of the associated flow area (and then the dimensions of the components), helium systems have to operate at high pressure, high velocity and with a larger difference between inlet and outlet temperatures. However, a large thermal difference makes the mechanical design more demanding in order to minimize potentially high thermal stresses, and, to sustain high volumetric flow, high pumping power is required so that the pressure drops have to be minimized. As helium is almost transparent to neutrons, it doesn't contribute to the shielding; this should be carefully considered in the blanket design, avoiding possible neutron streaming through penetrating pipes from the plasma side to the rear part of the structure. For blanket configurations of the first generation, it is proposed to use helium in a moderate temperature range of $300\text{--}500^\circ\text{C}$ (inlet-outlet) at a pressure of 8 MPa . Velocities of up to 80 m/s and turbulence promoters (Arbeiter et al., 2017) are required in the FW to remove high heat fluxes.

In spite of exceptional cooling characteristics (high density, low operational pressure, low volumetric flow, etc.), liquid metal cooling is highly penalized in MCF reactors. The presence of strong magnetic fields generates relevant magnetohydrodynamic (MHD) issues, such as very substantial pressure drops and turbulence suppression, that frustrate any other advantages (Smolentsev et al., 2010). In fact, electrical potentials are generated in the liquid metals as the result of interaction between the magnetic field and liquid flow. In particular, if electrically conducting materials such as steel are used for the containment structure, the conducting walls allow the closure of the flow path of eddy currents that interact with the magnetic field, producing forces that oppose the liquid movement. With a magnetic field of $4\text{--}9 \text{ T}$ experienced in the blanket, the velocity of liquid metal should be limited, in the worst case, to only several mm/s. The only way to allow a sufficient flow velocity (that is essential to reduce duct dimensions and increase heat transport) is to use ceramic structural materials (like SiC_f/SiC) or, alternatively, electrical insulators between the liquid metal and the metallic structure (e.g., alumina coatings or ceramic inserts). The attempt to develop this technology is illustrated in advanced blanket proposals such as the DCLL or SCLL blanket concepts (see Section "Blanket architecture").

Molten salts have been proposed as alternatives to liquid metal in order to maintain the same advantages in term of low pressure, low volumetric flow and the possible use as both coolant and breeder, while avoiding MHD effects. This is possible as their electrical conductivity is several orders of magnitude lower than that of liquid metals. The use of molten salts requires, however, a complex chemical control; the TBR is not exceptional, the melting temperatures relatively high and, in particular, they are extremely corrosive with structural materials. Even though blanket concepts based on the molten salt technology have been proposed several times since the 1970s, this technology has never provided the basis for a concrete DEMO design concept.

Neutron shielding

In the design of a blanket the neutron balance leading to a sufficient TBR is the high priority. To achieve this, the selection of blanket materials and their distribution in at least the first 50–80 cm are crucial to avoid large parasitic absorption. For instance, in a solid breeder blanket like the HCPB, 20% of the volume within the first 50 cm of the outboard region is occupied by ceramic breeder, while 50% is occupied by Be₁₂Ti, 15% by EUROFER steel and the rest helium. Suitable neutron performances can be realized with a compact and light design only, in which the structural part is dimensioned to be as thin as possible, manifolds of helium are avoided in the front region, and the mechanical structure is highly optimized to reduce steel content (which is responsible for the large parasitic neutron absorption).

Following this rationale, it is clear that the shielding is not the first priority in the design of the front part of the blanket. In this zone the neutron flux can be reduced by only a factor 10 without compromising the TBR. Once beyond it, the quantity of highly neutron-absorbing materials can be increased with the aim of satisfying shielding requirements. The first goal of the blanket shielding is to protect the vacuum vessel and in particular the mechanical and hydraulic attachment of the blanket to the vacuum vessel. Usually requirements are to reduce the cumulated dpa in an austenitic VV to lower than ~ 3 and to avoid excessive heating of the structures (to keep low temperatures in the design, enhancing safety features). Much lower values are of interest to reduce the VV activation and the large associated waste costs. In the design of particular components (e.g., welded piping connection or the entire VV) the production of helium via transmutation in steel should also be strongly limited; in fact, as a result of crack formation, values exceeding several at.% can already impede repair and maintenance operations that require welding of already irradiated material. The protection of the magnet systems is a further priority, but the vacuum vessel plays a major role in this respect; however, the blankets have to contribute to the shielding to reach the required plant limits: in DEMO this means a fast neutron flux lower than approximately $10^{13} \text{ m}^{-2} \text{ s}^{-1}$ and a power density than 50 W m^{-3} (Fischer et al., 2015).

Blanket concepts

Several blanket concepts suitable for the MCF FPR have been proposed since the 1980s based on different combinations of structural, coolant and breeder materials. However, the design has not evolved to more than a pre-conceptual level, where the feasibility of key technologies has not yet been fully demonstrated. ITER, the first thermonuclear device, will not be equipped with a Breeding Blanket, but only with a shielding structure (ITER “Shielding Blanket”), which is necessary to protect the vacuum vessel and magnets from the neutron flux and to remove the heat generated by the burning plasma. ITER will use only an external supply of tritium from fission reactors (about 16 kg for the entire possible operating lifetime (ITER Technical Basis, 2002)) and will not produce electricity using the relatively low water coolant temperature, which would make the process inefficient. For this reason, the design of this ITER component is almost irrelevant for the development of the breeding blanket, which is characterized, on the contrary, by the production of tritium and by high temperature coolant (at least greater than 300 °C) suitable for efficient electricity generation. Blanket technologies will, however, be tested in ITER in the form of small test blanket modules located in a few equatorial ports (see Section “The ITER test blanket program”).

Considering recent international developments, leading fusion communities, e.g., China, Europe, Japan and Korea, are proposing, as the next step after ITER, the construction of a national demonstration reactor based on the tokamak configuration. For this reactor, only few blanket concepts are under consideration using technology that seems achievable in the next 10–20 years. A common feature of these first-generation blanket concepts is the use of reduced activation ferritic martensitic (RAFM) steels as structural material; the development of these grades of steel has been started on a worldwide basis about 30 years ago with the ambitious target of withstanding neutron irradiation of more than 100 dpa and with activation characteristics that may allow their complete recycling in 100–200 years after FPR operation end. RAFM are 9Cr-steels that replace high activation elements (e.g., Mn, Ni, Mo) in the alloy with elements (e.g., W, V) that give corresponding material properties to the original alloy, but which have reaction products with a shorter half-life. These types of steels are under development by nations with a large fusion program using slightly different compositions: EUROFER in the EU (van der Schaaf et al., 2003), F82H in Japan (Jitsukawa et al., 2002), CLAM or CLM-1 in China (Huang, 2014) and ARAA in Korea (Chun et al., 2018). These materials have been produced already at semi-industrial scale, but the final in-pile characterization at high doses and, in particular, the definition of design rules that will make possible the final design is not yet complete, pending irradiation at fusion-relevant neutron energies. See (Litnovsky, 2021) for a more detailed discussion on fusion materials.

Based on these materials, manufacturing technologies for blankets have been tested in several programs. For the construction of the ITER TBMs these technologies are already being transferred at industrial scale, with final procurement foreseen towards the end of 2030. The technologies identified for the construction of the TBMs are, at present, the reference to which the DEMO manufacturing program is oriented; studies to extrapolate these technologies to DEMO conditions (e.g., large dimensions, longer irradiation time, stricter tolerances, reduced space, difficult inspection, etc.) have, at the moment, priority in the attempt to define a sound assembly route for these components. Taking into account the long time necessary for the qualification of a structural material for pressure vessel components within a nuclear environment, no materials other than RAFM steels are likely to be available for the structure of the first generation of breeding blankets. Alternatives, such as vanadium (Muroga, 2005) or SiC/SiC (Raffray, 1999), will be not qualified in this period, and typical ITER materials such as copper alloy and austenitic steel will not survive even the relatively low dpa levels foreseen for the proposed DEMO reactors (20–50 dpa). However, RAFM steels have critical issues, for

example, unexceptional thermal properties, which limit the heat flux that can be removed, and embrittlement under irradiation. In particular, the shift of the Ductile-to-Brittle Transition Temperature (DBTT) up to, or even above, room temperature during irradiation and the role of He-transmutation in increasing the total embrittlement are considered the most severe issues, and these are still not perfectly understood. What is known is that the major design parameter that impacts the damage is the operational (irradiation) temperature, which limits the dpa that the material can tolerate (and thus the operational lifetime). Only at relatively high irradiation temperatures (over 350–400 °C) is the shift in DBTT moderate (Gaganidze et al., 2006). Unfortunately, the temperature window—as foreseen for EUROFER in the present blanket concepts—ranges from 300 °C (even 285 °C, if water is used) up to 550 °C. Specifically, the worst conditions are at the front of the blanket, with the structure in contact with the coolant being at lower temperature but exposed to higher values of dpa. The issue is at present common to all the concepts; for blankets that use water cooling this level of temperature is intrinsic to the cooling regime adopted (where the temperature ranges over 285–335 °C in the PWR cycle). For blankets adopting helium cooling, the lower temperature can be increased, but this implies that the outlet temperature should be increased correspondingly to maintain a suitable ΔT to ensure high coolant performance; to accommodate these higher helium temperatures, the development of optimized RAFM steels for a higher operational window of, e.g., 400–650 °C, is required.

Blanket architecture

Fig. 2 show the typical architecture that has been developed for these first-generation blankets. The blanket is a box that contains the breeder, the coolant and shielding material. This box has a wall in front of the plasma referred to as the “first wall.” The rear part is a supporting structure, the “back plate”; the remaining walls are the side walls and two closing structures generally called “caps.”

The first wall (FW) protects the blanket from the plasma, removes the surface heat and confines the breeders and coolant; in addition, it must be relatively thin to avoid excessive absorption of neutrons before tritium breeding. High plasma radiation fluxes of 0.3–0.5 MW/m² have to be removed with an appropriate design of the first wall, which leads to a plate with a maximum of 30 mm thickness incorporating small cooling channels. In addition, interaction with the plasma ions and electrons of the SOL can produce local heat fluxes exceeding 5 MW/m² (Mitteau et al., 2013); taking into account constraints in the present structural materials (e.g., necessity of high neutron damage resistance or low activation criteria), these heat flux levels from the plasma cannot be accommodated with a solid wall (see 10 for similar considerations on an alternative “wetted-wall” design). For this reason, protection limiters are under development in the EU DEMO to limit the maximum local flux to values not exceeding about 1 MW/m², which is the limit of heat extraction with current technology using RAFM. The presence of an effective “limiter protection strategy” is critical for the realization of the present DEMO blanket concepts (Maviglia et al., 2018).

The zone beyond the FW and contained by the blanket box is the Breeding Zone (BZ). The function is essentially to breed tritium and remove heat, so that the main materials present in this region are the breeder/neutron multiplier (solid or liquid), the coolant

Fig. 2 Blanket architecture (functions of the various structures is described in the text).

and the structural material. All of the most-studied DEMO BB concepts share a common architectural design for the BZ: the breeder and the coolant are contained into two completely separate circuits with separate functions (“independent loop configuration,” see Fig. 3). The coolant loop (i.e., the Primary Heat Transfer System, PHTS) has the function to remove the heat; this heat has to be transferred to secondary systems that use it for electricity production. The coolant in these concepts is high pressure helium or water (8 and 15.5 MPa, respectively) at a temperature higher than $\sim 300^\circ\text{C}$. The breeder loop has to produce tritium and allow its

Fig. 3 Typical “independent loop configuration” for (A) a helium cooled solid breeder and (B) a lead-lithium water cooled blanket concepts.

transport (with a tritium carrier) outside of the vacuum vessel, where it will be pre-treated (e.g., tritium is removed from the carrier and concentrated) and sent to the Fuel Cycle. The advantage of this architecture is that tritium is concentrated in the carrier, where it can be more easily extracted/removed, avoiding dilution in the large volume of coolant. The coolant is not subject to direct contamination by tritium, and this both mitigates the issue of a potentially high tritium inventory accumulating (since achieving a simple and economic extraction would be challenging) and eliminates the possibility of tritium reaching the secondary circuit through a steam generator (if the direct cycle is used) or via a heat exchanger to a storage system (e.g., molten salts); should tritium reach the secondary loop, its possible release to the environment would be a major safety risk. A serious drawback of this configuration is the complex design of the blanket breeding zone, where the two loops are strongly interconnected. In fact, the coolant has to be distributed by capillary action to ensure the cooling of the breeder material; the coolant flows inside small tubes, or plates with channels, that are surrounded by the breeding materials. This means that a large surface will be necessary at the interface of the two independent loops (a figure of $\sim 13,000 \text{ m}^2$ is estimated in the whole blanket system for these concepts). This increases the design complexity (e.g., number and lengths of welding seams) and poses issues of tritium permeation from the breeder to the coolant loop.

Almost all of the most studied “near term” blanket concepts for DEMO follow this architecture; among these we can mention: the EU Helium Cooled Pebble Bed (Hernández et al., 2018), the Japanese Water Cooled Solid Breeder (Someya et al., 2019), the EU Water Cooled Lead-Lithium blanket (Del Nevo et al., 2019), the Chinese water-cooled blanket (Liu, 2019) and the Korean helium-cooled ceramic reflector blanket (Cho, 2018).

Various architectures have been proposed for advanced blanket concepts using different configurations for the breeder and coolant; the “self-cooled” configuration uses a coolant that is simultaneously the breeder; in this way the two loops can be unified and the overall design becomes very compact. The simultaneous transport of heat and tritium in a unique loop generates several concerns, however; as already noted, the tritium is diluted in the large volume of coolant and its removal necessitates very efficient plants with large dimensions. On the other hand, the high temperature of the coolant makes tritium confinement difficult; issues arise in the, potentially substantial, permeation into the steam generator/heat exchanger at the interface with the secondary systems. Fig. 4 shows an example of a self-cooled reactor that uses PbLi in the double function of coolant and breeder (Giancarli et al., 2003). In addition, a third configuration is the basis of a very interesting blanket concept developed in parallel in KIT (Germany) and in the United States, the “Dual coolant blanket.” This concept adopts two coolant circuits: one contains a pure coolant (usually helium) in direct contact with the steel structures, but the second uses a liquid breeder, as in in the “self-coolant” configuration. The electrical and thermal insulation between the two loops is ensured by means of insulating inserts (e.g., Alumina or SiC) inside the liquid breeder channels. This concept allows both the use of liquid metal cooling (at least for removing power generated in the breeder) and also the use of low temperature (up to 600°C) steels that are directly cooled by the non-(electrically) conducting coolant (i.e., helium). An example of a design using this blanket concept can be found in (Malang, 2011) and it is illustrated in Fig. 5.

The rear part of the blanket that contributes to closing the containment box is the back plate; this region has to incorporate the large manifolds for the coolant and the tritium carrier, the necessary shielding capability, the structural integrity of the blanket

Fig. 4 Self cooled configuration, as discussed in the text.

Fig. 5 Dual Coolant configuration, as discussed in the text.

replacement units for remote handling and the interface to the mechanical attachment system to the vacuum vessel. The design is strongly impacted by the concept of blanket replacement foreseen for the reactor; if a fully vertical maintenance concept (Keep et al., 2017) is adopted in DEMO, the back plate is a structure about 12 m high and 1.5 m wide, with a thickness of about 40 cm. It contains long poloidal manifolds to distribute the coolant and the tritium carrier to the FW and BZ from the connection to the external piping.

The ITER test blanket program

As already mentioned in Section “Blanket concepts”, ITER offers a unique opportunity to test blanket concepts in a full fusion environment before their application in a DEMO reactor. For this scope, two equatorial ports of ITER will be used to host blanket test objects (Giancarli et al., 2020). A Test Blanket Module has the dimension of about 1 m³ with a surface exposed to the plasma of about 1 m². Two of these objects can be allocated inside an ITER equatorial port and provided with independent coolant and tritium carrier loops; they will be fixed to the port plug structures that can be inserted into the equatorial port using the ITER standard transporter system. The port plug acts as primary containment insulating the TBMs from the rest of the device; only coolant, tritium carrier pipes and diagnostic lines are routed through the port plug to reach other locations in the ITER buildings that host, e.g., coolant systems, tritium extraction systems and diagnostic cubicles.

Each TBM reproduces the blanket architecture described in Fig. 2 and will use materials that are selected for a DEMO concept (e.g., use of RAFM steels as structural materials); the TBM consists of an external box that includes a BZ connected to specific coolant and tritium carrier loops. The BZ, in particular, is entirely DEMO-relevant, allowing experimental studies of structures, coolant, breeder/multiplier and tritium carriers under the same operational conditions (in terms of temperatures, pressures, flow velocities) as the DEMO blanket concept that is the subject of the test. In this respect, the fusion reactor conditions provided by ITER for neutrons and magnetic field intensity are not so different from those described for the DEMO (e.g., NWL of 0.78 MW m⁻² in comparison to ~1 MW m⁻² in the EU DEMO). Of course, the neutron fluences will be very limited in the ITER test, not more than 1 dpa in the FW structures for each irradiated TBM; this will allow a view of the behavior of the system in a “start of life” phase, but no information can be obtained for components at DEMO-relevant levels of integrated irradiation. The length of the pulses will typically be several minutes long, much shorter than the ~2 h foreseen for, e.g., the EU DEMO (though, in later phases of ITER operation, significantly longer pulses might be accessible as the ITER research program explores fully non-inductive long-pulse operation); this duration will be sufficient barely to reach temperature asymptotic conditions in all the blanket subcomponents and materials of interest.

A particularity of the TBM location in the port plug is that its FW is recessed by about 3 cm in comparison to the ideal FW surface dictated by the arrangement of the ITER shielding blanket. This implies that the exposure conditions of the TBM FW will involve strong “shadowing” by the other ITER FW systems and by the port plug. The TBM FW will be impacted only by (somewhat reduced) direct radiation from the plasma surface and will be almost completely shielded from the tangential plasma ion flux. How much the test can reproduce DEMO conditions (also if the “limiter protection” concept is adopted) it is an open point. In addition, the manifold and support elements of the TBM box are designed mostly to cope with the ITER requirements for interfacing with the port plug and to allow an easier access of diagnostic lines to monitor the TBM operational conditions.

A specific discussion is necessary for the use of RAFM in the TBM (Zmitko et al., 2017). Even if not strictly necessary for withstanding ITER irradiation conditions (as already mentioned they will not exceed several dpa in the entire lifetime), the test of these materials is a key aspect in the testing of the blanket system. For this, the TBM requires the development of manufacturing and joint technologies for this class of materials applied to a component design that follows the basic architecture of a blanket that will be adopted for a power plant.

The TBM auxiliary systems are designed to feed the TBM with coolant and tritium carrier at conditions comparable with DEMO in order to allow the full test of the blanket BZ. The technologies used in the cooling systems are not necessarily DEMO relevant: preference is given to standard proven technologies, robust, but perhaps not highly efficient for a large power plant. For example, helium-cooled TBMs (with a helium temperature of up to ~ 500 °C) use cooling loops with an 8-loop configuration with an intermediate recuperator that is typical for research loops where the helium blowers operate at low temperature (~ 50 °C), to reduce cost and simplify the operation mode. Tritium extraction technologies selected for the TBM (Ricapito et al., 2018) are essentially dictated by ITER (to limit the impact on the facility and to avoid jeopardizing the safety concept) and by the testing requirements (e.g., to perform accurate measurements of tritium species involved in the process). Once again, performance requirements are not of the highest priority, although several technologies are also incorporated to be tested in view of corresponding DEMO systems (e.g., GLC for tritium extraction from PbLi, or non-cryogenic systems for the tritium extraction of HT from the helium purge flow).

The role of TBM testing in the general DEMO development time schedule is a key consideration for the implementation of the ITER program. The DEMO programs of Europe, China and Japan have been proposed with the ambitious goal of starting operation in the middle of this century; the results of ITER (in terms of both device performance and TBM testing) should therefore be available on a timescale supporting this time schedule, as they are intended to guide and confirm the DEMO program. To what extent the development of the various DEMO sub-systems can be conducted separately from ITER, especially as concerns the development of those technologies that are not foreseen in ITER operation and testing (e.g., the fuel cycle architecture, with an “outer cycle” as discussed in Section “The fuel cycle”) remains under review. Even the present phase of the ITER TBM Program plays an important supporting role for the DEMO BB program via a constant Return of Experiences (RoX) in strategic topics such as the development of fabrication technologies (structural and functional materials), modeling tools, and safety and licensing concepts. In the 2030s, the TBM tests in ITER will allow the completion of out-of-pile integral testing with in-pile experiments where unique aspects of the fusion environment can be fully explored (e.g., neutron and magnetic field). A more detailed discussion of the scope of the TBM testing program and its benefits for the BB program can be found in (Poitevin et al., 2007).

Blanket for tokamak and stellarator

In the previous Sections the blanket has been described from the perspective of its application to a tokamak type MFC reactor, as is currently foreseen for DEMO, but this component is necessary also for the other possible MFC concepts, like the stellarator. The stationary operational mode of this reactor and the absence of major disruptions will simplify some loading conditions, but not in such a way that the general operational conditions will be so different from those in a tokamak; hence, the design principles of stellarator blankets will not differ much from what has been developed for the tokamak. However, the reactor integration will be more demanding, involving a fully 3D geometry in which the inherent axisymmetry of the tokamak configuration is absent. In addition, a blanket maintenance concept for stellarators has not yet been developed and faces the challenge of combining a complex geometry with intrinsically reduced space between magnet and plasma, and very limited space for large ports between the magnets for accessing the blanket position in the vacuum vessel. Only the absence of the internal solenoid and the large major radius—about 20 m in HELIAS (Warmer et al., 2016)—can, in principle, allow direct access to the VV also from the inboard side with ports. Overall, the stellarator blanket studies can be considered to be about 20 years behind those of tokamak reactors. Even if substantial elements of the blanket technology can be derived from the tokamak studies, further constraints due to the fully 3D geometry have not been studied in any depth and their consequences for the blanket technology are still not well understood.

Blanket for inertial fusion applications

As far as the breeding blanket for ICF reactors is concerned, very few specific power plant studies can be found in the literature; one such study was conducted in the framework of the ARIES-IFE (2004) to which we refer in this section. As in MCF reactors, it is assumed that a blanket with high coverage surrounds the ICF reaction chamber, with a thick BZ protected by a FW directly exposed to the D-T reactions. The major difference compared to MCF blankets is in the loading generated by the fusion process. In an ICF reactor, the driver energy (laser or heavy ion beam) induces a thermonuclear reaction via the implosion of single D-T target; a pulse

of fusion energy (from some tens to some hundreds of MJ) is released in a single target implosion on the nanosecond time scale; the repetition frequency of the implosions is in the range of 5–15 Hz. Depending on the target design and materials, several reactions can occur which determine the final composition of the particles and radiation emerging from the target: in the typical targets considered in the ARIES-IFE, $\sim 70\%$ of the energy is transported by neutrons that will reach the FW of the reactor chamber, penetrating it and depositing their energy into a large blanket BZ. Apart from a slight difference in the neutron spectra caused by the target interaction, the principles of thermal deposition (and nuclear reactions) in the blanket volume are similar to those already discussed in relation to the MCF blankets and can be accommodated by standard BZ technology. The major difference relating to blanket design is the absence of magnetic fields (and of the external structures associated with the magnets and their supports), which can enable an efficient design based on liquid metal cooling and facilitate the accessibility of blanket component from outside the reaction chamber; these features could simplify the design, even if the complex arrangement of laser or heavy ion beams imposes other constraints associated with the conflicting requirements of providing simultaneously external penetration for the beams and confinement and shielding of the internal reaction products.

A major difference with magnetic fusion reactors relates to the transport of the remaining 30% of the emitted energy; this will be divided between the kinetic energy of ions and soft X-rays (< 1 keV); both energy contributions will be absorbed in the chamber FW as surface heat flux, almost entirely within the first 100–200 μm of FW material. The short deposition time (i.e., nanoseconds) of this energy presents a key challenge, since the energy pulse can produce ablation (e.g., evaporation) in a solid surface; at a deeper level within the FW, the heat flux tends to become uniform in time due to the thermal capacity of the wall materials, converging to absolute values comparable with those in MCF devices. In ICF reactors, the energy emitted in the form of X-rays can reach $\sim 25\%$ of the total fusion energy released in the case of indirect-drive targets (using high-Z materials in the target hohlraum to increase the yield of the reaction); in direct-drive targets the ions tend to retain their energy so that only a small fraction ($\sim 1.5\%$) of the energy is transmitted as X-rays. As all photons transport energy to the first wall on the same nanosecond-timescale, the resulting power deposition can be very severe; in contrast, ion energy (of fusion reaction products and target debris) is emitted with a wide range of energies and speeds, so that the deposition time scale is expanded to the microsecond-scale, reducing the first wall ablation per shot. In addition, the chamber environment (i.e., presence of residual products of previous reactions or buffer gases) can play an important role in modifying the load; i.e., the controlled use of a sufficiently dense high-Z gas, xenon as described in (Dunne et al., 2011), can efficiently protect the FW from X-rays via reactions that can disperse the energy pulse over a period of several microseconds. To what extent the use of buffer gases is compatible with the propagation and focusing of driver beams, as well as the survivability of the targets, must be further investigated.

This explains why ICF blanket studies have focused on FW heat removal and protection (“chamber concepts”). The issue of FW protection has emerged as a driving requirement in the design of this component and in the material selection (Alvarez et al., 2011). In particular, the use of indirect-drive targets (high X-ray content in the resultant heat flux) brings the technology of solid walls (“dry-wall”) to its limits (Najmabadi et al., 2004). For this reason, alternative solutions have been proposed adopting, e.g., the “wetted-wall” technology, where the supporting FW structure is protected by an external liquid film that acts as a renewable armor; if the liquid is selected from among potential liquid breeders (liquid metals or molten salts) the neutronics aspects of the design can be optimized, avoiding any extraneous materials. Here, two different concepts can be adopted to create a protective liquid film: (a) a porous FW structure that allows the injection into the reaction chamber of the liquid to compensate the evaporation and maintain a thin protective film, or (b) a forced flow of a liquid film tangential to a solid wall that supports and drives it. In case (b) the absence of magnetic fields allows a better use of liquid metals, avoiding large MHD flow instabilities, a key issue for MCF applications. But this is the only advantage: in general, the use of a “wetted-wall” technology encounters many open questions on the film dynamics, tritium compatibility, compatibility with and recovery of evaporating liquid in the reaction chamber, etc.

An integrated ICF power plant design with breeding blankets can already be found in the literature more than 25 years ago, the HYLIFE-II baseline (Moir, 1994). The paper proposes the use of a “waterfall” of FLiBe for wall protection and heat removal; the FLiBe flow is then passed into a heat exchanger where it heats water for use in the turbines. FLiBe acts also as tritium breeder and neutron multiplier: the tritium produced in the reaction with lithium is also extracted in the external loop in order to close the power plant’s thermonuclear fuel cycle.

An example of a “dry-wall” chamber is presented in (Garoz, 2016): in this paper the behavior of a tungsten first wall is studied under the irradiation conditions predicted for HiPER (High Power Laser Energy Research Facility) with direct drive targets.

Glossary

Beta normalized Operational parameter indicating how close a tokamak plasma is to reaching the empirical pressure limit, involving, in some cases, destabilization of a major magnetohydrodynamic (MHD) instability.

Bootstrap current A self-generated current due to collisions between trapped and passing plasma particles. The bootstrap fraction is strongly influenced by the density gradient.

DCLL Dual-Coolant Lithium Lead—one of the possible concepts for the tritium breeding blanket.

Disruption In a disruption the plasma confinement is lost in milliseconds. Often this occurs after a vertical displacement event of the plasma column or after the growth of non-axisymmetric magnetohydrodynamic instabilities.

ECRH Electron Cyclotron Resonant Heating.

Edge Localized Mode (ELM) Magnetohydrodynamic instability in the plasma edge region associated with a quasi-periodic relaxation of the edge transport barrier formed during the transition from low (L) to high (H) confinement mode.

Greenwald scaling Empirical upper limit for the central line-averaged density in a tokamak plasma which depends on plasma current and minor radius.

HCCB Helium-Cooled Ceramic Breeder—one of the possible concepts for the tritium breeding blanket.

HCLL Helium-Cooled Lithium Lead—one of the possible concepts for the tritium breeding blanket.

HCPB Helium-Cooled Pebble Bed—one of the possible concepts for the tritium breeding blanket.

HTSC High-temperature superconductor.

ICRF Ion cyclotron radiofrequency heating.

IFMIF/DONES International Fusion Materials Irradiation Facility/DEMO Oriented Neutron Source.

IFMIF/EVEDA International Fusion Materials Irradiation Facility/Engineering Validation and Engineering Design Activities.

LHH Lower hybrid heating.

LTSC Low-temperature superconductor.

Martin scaling Empirical scaling for the input power to the plasma required to access the H-mode.

NBH Neutral Beam Heating.

Snowflake divertor A divertor geometry that effectively spreads the heat load from the plasma over four instead of over two footprints, thereby effectively lowering the heat load on the divertor materials.

WCLL Water-Cooled Lithium Lead—one of the possible concepts for the tritium breeding blanket.

Introduction—The path towards fusion electricity

A number of countries have developed fusion roadmaps or strategic plans, in order to clarify which steps need to be taken to achieve electricity generation from fusion (Donné et al., 2018; Okano, 2019; Wan et al., 2017; National Academy of Sciences, 2019). Although there are differences between the various fusion roadmaps, there are also many commonalities, which are depicted in Fig. 1. All roadmaps include ITER (Bigot, 2019) as an essential step. ITER will demonstrate that energy from fusion is feasible by aiming at a plasma power multiplication ($Q = P_{\text{fusion}}/P_{\text{in}}$) of 10 and it will demonstrate essential fusion technologies, such as tritium breeding.

A second important facility included in basically all roadmaps is the demonstration reactor that will for the first time deliver electricity to the grid. In Europe and Japan this device is named DEMO (Federici et al., 2018; Tobita et al., 2019), in Korea K-DEMO (Kim et al., 2015), and in China it is known as the China Fusion Experimental Test Reactor (CFETR; Zhuang et al., 2019). These devices are all based on relatively conservative extrapolations from ITER following the rationale that obtaining a nuclear license for a new device is facilitated by exploiting technologies and components that have already been demonstrated elsewhere. Reactors following DEMO and CFETR are foreseen as first-of-a-kind fusion power plants (FPPs).

Some countries, however, prefer to pursue smaller, more flexible, facilities based on spherical tokamaks to follow ITER (Menard et al., 2016), such as the Fusion Nuclear Science Facility (FNSF; Kessel et al., 2018) in the USA and the Spherical Tokamak for Energy Production (STEP; Wilson, 2020) in the UK. Most likely these facilities must be followed by a real demonstration plant, before fusion can be commercialized. Several privately funded enterprises (Sykes et al., 2018; Sorbom et al., 2015) are also following this approach, with the special feature that high-temperature superconducting magnets are proposed to make it possible to build rather small fusion reactors, featuring a high power density. In a certain sense one could say that these approaches are depicted by the green line in Fig. 1.

Since the neutron fluence in the devices following ITER (e.g., DEMO and CFETR) will be much higher than those in ITER, new materials need to be developed and validated. At present, this is largely pursued in Materials Test Reactors (basically fission reactors), but for testing the plasma facing components an intense neutron source with a dedicated fusion neutron spectrum is needed. The International Fusion Materials Irradiation Facility (IFMIF) is such a facility, and prototype components are presently being tested in a collaboration between Europe and Japan (Knaster et al., 2017). To accelerate the path to the realization of such a neutron source, Europe and Japan are now each proposing smaller neutron sources, IFMIF/DONES in Europe (Ibarra et al., 2018), and the Advanced Fusion Neutron Source in Japan (Ochiai et al., 2020). Spherical tokamak based devices have also been proposed as volumetric neutron sources, denoted ‘Component Test Facility’.

Fig. 1 Schematic view of the main elements of a fusion roadmap that is common to several countries. The stellarator line is mainly in the European and Japanese roadmaps.

As indicated by the red arrows in Fig. 1, many operational facilities within the international fusion research program are providing input to ITER and to DEMO. Tokamaks predominate, but devices such as stellarators also give important input to the main fusion roadmap. All devices limit operation to hydrogen and deuterium plasmas to minimize nuclear activation, facilitating upgrades and the continuous evolution of experimental capabilities. The Joint European Torus (Joffrin et al., 2019), nevertheless, retains a capability for experiments with deuterium-tritium plasmas. As discussed later, several significant new non-nuclear facilities are currently in the development phase: JT-60SA, a Japan-EU collaboration (Barabaschi et al., 2019), the Divertor Test Tokamak (DTT) in Italy (Albanese et al., 2019), HL-2M (Song et al., 2019) in China and COMPASS-Upgrade (PANEK et al., 2017) in the Czech Republic.

This chapter is organized as follows. Section “ITER” briefly describes the key objectives, design features, major component systems and overall research framework of the ITER project. Section “Demonstration reactors” summarizes the major considerations influencing the design of demonstration reactors based on conservative extrapolations from ITER (the DEMO reactors by Europe, Korea and Japan and the Chinese CFETR), discusses a range of concepts developed within the framework of the ‘Fusion Nuclear Science Facility’ and ‘Pilot Plant’ studies, the majority based on the spherical tokamak configuration and several seeking to exploit recent developments in high temperature superconductors, and finally comments on key prospects for stellarator-based DEMO reactors. Conceptual designs for facilities intended to provide a nuclear irradiation capability for fusion materials and components are described in section “Fusion materials test facilities”, while several of the non-nuclear facilities under development are briefly discussed in section “Non-nuclear development facilities”.

ITER

Introduction

ITER is the next step fusion device, and at this moment the largest international scientific project world-wide (ITER, 2002; Bigot, 2019). It is a collaboration between China, the European Union (including Switzerland), India, Japan, South-Korea, the Russian Federation and the United States. The initial ITER collaboration was launched in November 1985 at the Geneva summit meeting between Secretary-General Gorbachev of the Soviet Union and President Reagan of the United States. After two decades of design studies, R&D and international negotiations, the ITER Agreement among the seven members was signed in November 2006 and the ITER Organization was officially established in October 2007 with its headquarters at the ITER construction site in St Paul-lez-Durance, southern France. The history of ITER is described in Ikeda (2010) and Claessens (2020).

As cited in the ITER Research Plan (ITER Organization, 2018), the ITER scientific goals, defined in terms of plasma fusion performance, are:

- ITER should achieve extended burn in inductively driven plasmas with the ratio of fusion power to auxiliary heating power, Q , of at least 10 ($Q \geq 10$) for a range of operating scenarios and with a duration sufficient to achieve stationary conditions on the timescales characteristic of plasma processes.
- ITER should aim at demonstrating steady-state operation using non-inductive current drive with the ratio of fusion power to input power for current drive of at least 5.
- In addition, the possibility of controlled ignition should not be precluded.

The technical goals, aiming to provide much of the technological basis for the design of future fusion power plants capable of generating electricity, are:

- ITER should demonstrate the availability and integration of technologies essential for a fusion reactor (such as superconducting magnets and remote maintenance).
- ITER should test components for a future reactor (such as systems to exhaust power and particles from the plasma).
- ITER should test tritium breeding module concepts that would lead in a future reactor to tritium self-sufficiency, the extraction of high-grade heat and electricity production.

Demonstration of the safety and environmental advantages of fusion energy is a further significant aspect of the ITER project mission. In this respect, it should be noted that ITER has undergone the full licensing procedure appropriate to a ‘Basic Nuclear Installation’ (INB) within the French nuclear regulatory system (see, e.g., Taylor et al., 2013). The French Government granted the Decree of Authorization of a nuclear facility in November 2012 and ITER is now established as INB-174 within the French regulatory framework.

A cutaway view of the ITER tokamak is given in Fig. 2 and the main parameters of the ITER-plasma are listed in Table 1. Extensive details on the ITER design and its technical systems can be found in papers published during the project’s design and R&D phase, e.g., (ITER, 2002; Aymar et al., 2002; Shimomura, 2001), while more recent developments in ITER technology are discussed by Campbell et al. (2019).

Tokamak core systems

As illustrated in Fig. 2, the principal tokamak core components are the vacuum vessel, plasma-facing components (divertor and shielding blanket/first wall), in-vessel control coils, superconducting coil systems (toroidal field (TF), poloidal field (PF), central solenoid (CS) and correction (CC) coils), thermal shield and cryostat.

Fig. 2 Schematic view of the ITER tokamak with the main components indicated. Copied with permission from Campbell DJ, Akiyama T, Barnsley R, et al. (2019) Innovations in Technology and Science R&D for ITER. *Journal of Fusion Energy* 38: 11–71. <https://doi.org/10.1007/s10894-018-0187-9> (web archive link,).

Table 1 Main parameters of ITER.

Parameter	Value
Major radius, R_0 (m)	6.2
Minor radius, a (m)	2.0
Toroidal field on axis, B_T (T)	5.3
Plasma current, I_p (MA)	15
Plasma elongation, κ	1.85
Plasma triangularity, δ	0.49
Edge safety factor, q_{95}	3.0
Neutral beam power, P_{NB} (MW)	33
Radiofrequency power, P_{RF} (MW)	40
Fusion power, P_{fusion} (MW)	500
Fusion gain, Q	10
Burn time (s)	300

The ITER vacuum vessel (Martinez et al., 2016), consisting of the main vessel, port structures and supporting system, provides a hermetically sealed plasma container which also fulfils the critical role of first tritium containment barrier. It is a water-cooled austenitic stainless steel (SS 316L(N)) pressure vessel with an outer diameter of 19.4 m, a height of 11.4 m and an inner volume of 1400 m³. The main vessel is a double-walled steel structure strengthened by interspace stiffening ribs, with the space between the two 60 mm walls filled by ‘in-wall’ shielding in the form of modular blocks of borated and ferromagnetic steel. These blocks contribute additional neutron shielding for components external to the vacuum vessel (e.g., the superconducting magnets), while also reducing the toroidal field modulation (‘ripple’) caused by the finite number (18) of toroidal field coils. 44 ports in the vessel (18 upper, 17 equatorial and 9 lower ports) allow access for diagnostic systems, neutral beam injection, radio-frequency heating, fueling and vacuum pumping, as well as providing access for remote handling systems used for maintenance and repair. The total weight of the vacuum vessel, including ports and in-wall shielding is approximately 5200 tons.

The inner walls of the vacuum vessel, with an area of ~ 600 m², are covered by 440 actively-cooled shielding blanket modules that protect the vacuum vessel and the superconducting magnets from the heat and neutron fluxes produced by fusion reactions. Each water-cooled blanket module, fabricated from 316L(N) stainless steel, has a plasma facing surface area of ~ 1.5 m², is ~ 45 cm thick radially and weighs up to 4.5 t. The blanket cooling water system operates at 4 MPa, with an inlet temperature of 70 °C, and is capable of removing 750 MW of thermal power. A detachable first wall, fabricated from 8 to 10 mm thick beryllium, is mounted on

the module plasma facing surface to intercept heat fluxes arriving in the form of plasma particles and electromagnetic radiation. Beryllium has been selected as the first wall material due to its low atomic number, which limits plasma contamination, and low affinity for hydrogenic isotopes, which limits fuel retention.

The divertor extracts heat, helium ash produced by the fusion reactions, unburned fuel and impurities in such a way that plasma contamination is minimized. It is formed from 54 stainless steel cassettes, each weighing ~ 8 t, arranged to form a toroidal ring. Plasma facing surfaces ('divertor targets') are mounted on the inboard and outboard regions of the cassette designed to withstand steady state heat fluxes of 10 MW m^{-2} and slow transients of up to 20 MW m^{-2} , while the 'dome' region lying between the inner and outer targets can handle heat fluxes of up to 5 MW m^{-2} . Solid tungsten, ~ 8 mm thick, forms the plasma facing surfaces, due to its high melting point, low sputtering yield under plasma bombardment and low fuel retention. High pressure water cooling is used for heat exhaust, as for the shielding blanket.

The superconducting magnet systems consist of 18 TF coils and 6 CS modules wound from Nb_3Sn superconductor plus 6 PF and 18 CC coils fabricated from NbTi superconductor. All coils are cooled with supercritical helium at temperatures in the range 4.2–4.5 K. The D-shaped TF coils are 17 m high and 9 m wide, and each weighs ~ 330 t. They are wound in 'double pancakes'—layers of spiraled conductor embedded in radial plates and each TF winding is encased in stainless steel. The maximum magnetic field on the coil is 11.8 T and, when fully energized, the total magnetic energy of the TF is 41 GJ. The ring-shaped PF coils, the largest having a diameter of 24 m, are mounted outside of the TF coils and operate at a maximum magnetic field of 6 T at the coil. The CS coil, with an overall height of 13 m and weighing ~ 1000 t, consists of six independent modules, each 4 m in diameter. With a maximum magnetic field of 13 T in the center of the coil stack and a stored magnetic energy of 6.4 GJ, the CS can sustain a 15 MA plasma current for 300–500 s during a high power fusion burn. The CC are much lighter, as they simply compensate for residual magnetic field errors, but the largest of these nevertheless have an area of $8 \times 8 \text{ m}^2$. An overview of the ITER magnet system is provided by Mitchell and Devred (2017), while Devred et al. (2014) describe the challenges in the production of the superconductor.

The height and diameter of the ITER cryostat (Sekachev et al., 2015; Bhardwaj et al., 2016) are both ~ 30 m, while the structure, including the thermal shields, weighs ~ 4000 t. With an internal volume of $16,000 \text{ m}^3$, this stainless steel pressure vessel provides the high vacuum ($\sim 10^{-4}$ Pa), cryogenic environment for the ITER tokamak core components, in particular the superconducting magnets. The cryostat has over 200 penetrations to allow for maintenance access and replacement of blanket modules and divertor cassettes, and to provide access for heating systems, diagnostics, cooling systems, and magnet feeders. It is connected to the vacuum vessel via large bellows that allow for thermal contraction and expansion during ITER operation.

Auxiliary and plant systems

To achieve the initial conditions for achieving high fusion gain, three auxiliary heating and current drive (H&CD) systems provide a total baseline heating power of 73 MW (Singh, 2016):

- Two Neutral Beam Injectors (NBI) (Hemsworth et al., 2017) will provide a total input power of 33 MW, with provision for a third injector to allow a total beam input power of 50 MW. The injectors are based on negative ion technology (Inoue et al., 2021) operating at 1 MeV injection energy, allowing central deposition of the beam power. Near-tangential injection into the plasma allows torque input and current drive.
- The Ion Cyclotron Radiofrequency Heating (ICRH) system (Beaumont et al., 2017) injects 20 MW of power with a frequency in the range 40–55 MHz from two antennas located in the equatorial port plugs.
- The Electron Cyclotron Resonant Heating (ECRH) system (Darbos et al., 2016) will deliver 20 MW of power to the plasma at a frequency of 170 GHz. The gyrotron power sources are each designed to deliver 1 MW for periods of at least 1000 s. The ECRH power is injected into the plasma via launchers with steerable mirrors located in both the upper and equatorial ports of ITER.

A nominal input power level of 50 MW is foreseen for sustainment of the reference burning plasma scenario, which is predicted to generate 500 MW of DT fusion power:

ITER will have approximately 55 different diagnostic measurement systems to measure a large range of plasma and machine parameters (Donné et al., 2007; Walsh et al., 2015). The diagnostics are classified into three groups: (i) diagnostics for basic operation and machine protection, (ii) diagnostics for advanced control and (iii) diagnostics for physics evaluation and performance optimization. A large range of different diagnostic techniques is used (Inoue et al., 2021), for example, magnetic measurements, neutron emission measurements, optical systems, radiation bolometers, spectroscopy across the electromagnetic spectrum, microwave emission, transmission and reflection, and plasma-facing and operational diagnostics. For some diagnostics, the detectors must be mounted inside the vacuum vessel and great emphasis is given to ensuring their radiation hardness. Most in-vessel detectors are located deep in slots between adjacent blanket modules, to provide protection against the hostile plasma, while some diagnostics for plasma edge measurements are mounted on the divertor cassettes. Many other diagnostics have optical or microwave interfaces incorporated into dedicated vacuum vessel port plugs with complex folded optical or microwave transmission lines to reduce neutron streaming through the port plugs. Detectors and active sources, such as lasers and microwave generators, are then located in the diagnostics building, far from the plasma. The hostile environment within the proximity of the plasma necessitates the development and application of in-situ techniques to counteract the effects of plasma bombardment of the first, plasma facing, mirrors in many optical systems, ensuring high reflectivity of the mirror surface.

A sophisticated plasma control system (PCS) combines measurements made by these diagnostic systems to sustain fusion power production via real-time control of the plasma parameters implemented via various ‘actuator’ systems, i.e., magnet systems, H&CD systems, fueling and impurity injection systems (Snipes et al., 2017). At high plasma performance, the control of magnetohydrodynamic (MHD) instabilities (Lao et al., 2021) is particularly critical in ITER to maintain the fusion burn and to avoid potential damage to the first wall. For example, edge localized modes (ELMs), which expel short bursts of heat and particles, are controlled by a set of 27 in-vessel copper coils (Vostner et al., 2019). Disruptions, which produce high transient heat and electromechanical loads on in-vessel structures, must be avoided or their effects mitigated (see Lao et al., 2021; Zohm, 2021). A dedicated system, based on fragmentation of cryogenic deuterium or noble gas pellets, and referred to as Shattered Pellet Injection, SPI (Lehnen et al., 2015) will operate under PCS control to implement disruption mitigation. The PCS can also control the injection of localized H&CD to suppress MHD instabilities responsible for triggering disruptions.

Demonstration of the feasibility of producing tritium within the reactor system is a key mission of ITER, and the project will provide a unique opportunity to test prototypical in-vessel tritium breeding blankets in a real fusion environment (Giancarli et al., 2018). Several concepts for tritium breeding and high grade heat extraction will be tested in ITER using two dedicated port plugs, each allowing two distinct ‘test blanket module’ (TBM) designs to be exposed to the fusion neutron flux. Initially, two TBMs are planned to use water-cooling and two helium-cooling. Further details of the ITER TBM program are discussed by Boccaccini et al. (2021).

The ITER plant systems provide key services to the tokamak and its auxiliary systems, and, in many respects, are constructed on a scale commensurate with that required in a fusion power plant. Plant systems include the Fuel Cycle (fueling, vacuum, exhaust gas reprocessing), Remote Handling, Cryopant, Cooling (water cooling systems, heat exchangers, waste heat exhaust), Power Supplies (steady-state and pulsed) and Waste Processing (including detritiation).

As noted above, ITER will test concepts for tritium breeding. However, the significant amount of tritium fuel, ~ 14.5 kg over a period of ~ 20 years, required meet the project lifetime goal of achieving an average first wall neutron fluence of 0.3 MW yr m^{-2} means that tritium must be externally supplied from existing civil fission stockpiles and that fuel reprocessing on an unprecedented scale will be required to ensure efficient consumption of tritium. A large-scale tritium reprocessing plant therefore forms the core of the ITER Fuel Cycle system (Boccaccini et al., 2021): an annual tritium reprocessing capability corresponding to ~ 25 times the onsite tritium inventory will be required. A substantial high vacuum pumping capability is a further critical element. The total volume of the ITER vacuum system (Day et al., 2008) exceeds $10,000 \text{ m}^3$ (cryostat: 8500 m^3 , vacuum vessel: 1330 m^3 , neutral beam injectors: 180 m^3 each). The central part of the roughing system consists of newly developed cryogenic viscous flow compressors in combination with Roots mechanical pumps, while the facility also features a set of six cryopumps for the main vacuum vessel, four for the neutral beam system and two for the cryostat. These pumps, cooled by supercritical helium, are coated with activated charcoal as sorbent material, in particular for helium pumping. Finally, fueling of DT plasmas by gas injection and cryogenic pellet injection closes the fuel cycle. Further considerations related to the design of reactor-scale fuel cycle systems can be found in Boccaccini et al. (2021).

ITER is equipped with one of the world’s largest cryopants (Monneret et al., 2017)—only the distributed system for the Large Hadron Collider has a greater cooling capacity. It consists of two large nitrogen refrigerators and three large helium refrigerators, which provide the necessary cooling for the superconducting magnets. It also supplies the six cryopumps that operate at a temperature of 4 K, the magnet current leads that operate at 50 K and the thermal shields within the cryostat that are cooled to 80 K. The installed cooling power is 75 kW at 4.5 K (helium) and 1300 kW at 80 K. The ITER tokamak and the auxiliary systems will produce on average 500 MW of heat during a typical plasma pulse cycle, with a peak of 1.1 GW during the plasma burn phase, and this needs to be dissipated to the environment. Heat generated by the plasma is transferred via the Tokamak Cooling Water System, TCWS (Lioce et al., 2019), to the intermediate Component Cooling Water System (CCWS; Kumar et al., 2013), which is a closed loop system that transfers the heat to the Heat Rejection System (HRS). Water from the HRS is ultimately discharged into the nearby canal after monitoring to ensure that it fulfils the stringent environmental release criteria.

Robust remote handling techniques are being developed to support in-vessel maintenance and repairs (Damiani et al., 2018; Federici et al., 2021). Special remote handling tools will be able to replace heavy components such as the blanket modules, divertor cassettes and the port plugs, with weights of up to 50 tons. A substantial Hot Cell Facility, HCF (Friconneau et al., 2017), will permit maintenance and processing of irradiated and tritiated components that have been removed from the tokamak. Transportation between the tokamak and the HCF will be carried out using a sealed transport cask. Radioactive waste will be produced during ITER operation and decommissioning (Rosanvallon et al., 2016) due to the replacement of components, as well as from process and housekeeping waste. The waste consists of components activated by neutrons with energies of up to 14 MeV, and contaminated by activated corrosion products, activated dust (including beryllium and tungsten dust) and tritium. To satisfy French regulatory requirements, facilities are included in the ITER Hot Cell complex for the treatment and interim storage of the waste. This complex, equipped with an extensive remote handling capability, will provide a secure environment for the processing, repair or refurbishment, testing, detritiation and disposal of activated ITER components.

ITER research plan

The ITER Baseline Schedule foresees a phased transition from facility construction to plasma operation (the ‘Staged Approach’), with the scope of the associated research program, as defined by the ITER Research Plan (IRP) (ITER, 2018), expanding as the facility capabilities are increased over a period of approximately 10 years (Fig. 3). Within the IRP, these first 10 years of ITER operation are

Fig. 3 Schematic time sequence of the first 10 years of ITER operation in the Staged Approach. Adapted with permission from Fig. 5 of Campbell DJ, Akiyama T, Barnsley R, et al. (2019) Innovations in Technology and Science R&D for ITER. Journal of Fusion Energy 38: 11–71. <https://doi.org/10.1007/s10894-018-0187-9> (web archive link,).

sub-divided into three phases: First Plasma (FP), Pre-Fusion Power Operation (PFPO, subdivided into two stages) and Fusion Power Operation (FPO). During the FP and PFPO phases ITER will operate only with hydrogen and helium plasmas, while the FPO phase will focus on optimization of fusion power production in DT plasmas.

During the First Plasma phase, scheduled for late 2025 and targeting plasma currents in the range 100–500 kA, the magnets, the vacuum vessel and the cryostat will be qualified and the most basic auxiliary systems commissioned. These commissioning and experimental activities terminate in an Engineering Commissioning phase to commission the superconducting magnet systems to full current. The PFPO-I and PFPO-II programs are dedicated to a phased commissioning of key hardware systems associated with a gradual increase in plasma parameters and in the sophistication of plasma operating scenarios. Thus, the blanket modules/first wall, divertor, full ECRH system and a range of diagnostic and dedicated control systems will be installed in advance of PFPO-I, allowing routine operation at plasma currents of up to 7.5 MA and toroidal fields in the range 1.8–5.3 T with heating powers of up to 20 MW. A range of plasma operating regimes and plasma control schemes, including disruption avoidance and mitigation, will be commissioned and explored during this program. The full H&CD capability and an extended set of diagnostic systems will be added in advance of PFPO-II. This will support operation at full technical performance (15 MA/5.3 T) with up to 73 MW of heating power and the implementation of an extensive program of plasma and plasma control scheme development, with plasma pulse durations of at least 100 s, in preparation for the transition to DT plasma operation.

Long-range plans foresee final preparations for DT operation being made in 2034–2035, including the final commissioning of the DT fuel cycle and the installation of additional DT-relevant diagnostics. Following authorization by the nuclear authorities, deuterium plasma operation would be launched in early 2035, followed by the transition to full DT operation in the course of 2035. Operating on a two-year cycle of 16 months plasma operation and 8 months maintenance, a series of experimental campaigns would explore optimization of fusion power production in a range of ‘baseline’ plasma scenarios, as detailed in Table 2. Initially, the program is planned to address the achievement of a fusion gain, Q , of at least 10 at fusion powers of up to 500 MW using nominal plasma parameters of 15 MA/5.3 T, and with the burning plasma duration being extended towards the range 300–500 s as operational experience accumulates. Alternative scenarios which current experiments indicate as particularly promising include the ‘hybrid’ scenario, operating in the range 12–14 MA with a significant component of non-inductive current drive. A further key aim of the DT experiments is the achievement of fully non-inductive steady-state plasma operation at lower plasma currents, ~ 9 MA, with $Q \geq 5$ and pulse durations of up to 3000 s.

Table 2 Main parameters of the ITER baseline reference scenarios (Campbell et al., 2019).

Parameter	Inductive	Hybrid	Non-inductive
Plasma current, I_p (MA)	15	13.8	9
Energy confinement time, τ_E (s)	3.4	2.7	3.1
Confinement enhancement $H_{98}(y,2)$	1.0	1.0	1.6
Pressure figure of merit, β_N	2.0	1.9	3.0
Average electron density $\langle n_e \rangle$ (10^{19} m^{-3})	11.3	9.3	6.7
Fusion power, P_{fusion} (MW)	500	400	360
Fusion gain, Q	10	5.4	6
Burn time (s)	300–500	> 1000	~ 3000

While the fully non-inductive steady-state scenario (i.e., with zero flux swing in the CS) is anticipated to provide the operational basis for future fusion reactors, ITER can also explore alternative operating scenarios to those listed in [Table 2](#), whether developed in ongoing experiments in smaller devices, or in ITER's experimental program. The DT operations phase will, in addition, incorporate significant fusion technology studies in support of DEMO and future reactors, the most significant being the demonstration of tritium breeding and high grade heat extraction from the TBMs which will be exposed to the DT neutron flux.

Demonstration reactors

Background

With the ITER project well under way, the nations engaged in magnetic fusion R&D are now determining the necessary science and technology developments required to harness fusion energy. This includes, primarily, progression towards a device capable of demonstrating the production of few hundred MW of net electricity, feasibility of operation with a closed-tritium fuel cycle, maintenance systems capable of achieving adequate plant availability, a high level of safety and low environmental impact. This is known as a DEMOnstration Fusion Power Plant (DEMO).

Europe and Japan envision that ITER should be succeeded by the construction and exploitation of DEMO, the final step before the first commercial power plant. A dedicated divertor test tokamak (DTT), to investigate the problem of power exhaust and demonstrate performance of advance divertor solutions, and a neutron-irradiation facility to qualify materials (IFMIF-DONES) are included in this strategy. Stellarators are also being pursued, the largest devices being LHD (Japan) and Wendelstein 7-X (Europe). China has an ambitious plan to exploit fusion energy for electricity production as quickly as possible to offset the foreseeable large increase in energy demand. The “Chinese Fusion Engineering Test Reactor (CFETR)” facility is currently in the conceptual design development phase with construction planned by the end of the 2020s. South Korea has begun pre-conceptual design work on a DEMO device to develop technology solutions, denoted ‘K-DEMO-1’, with the intention of starting construction in the late-2020s and beginning operation in 2040. After a reconfiguration of the internal components, the second phase (‘K-DEMO-2’) will be launched, leading to a full demonstration of industrial scale electricity generation from a fusion plant. Other communities, e.g., the US and India, view DEMO as the last step before commercialization, but both consider that an intermediate step between ITER and DEMO is required. There is considerable deliberation over the scope of such a device and delay in exploiting fusion energy implied by an additional intermediate step is an issue. Finally, the Russian Federation is considering both ‘pure’ fusion machines and fission–fusion hybrids in their strategy.

The construction, commissioning and operation of ITER are central elements in all fusion development roadmaps. However, while the contribution of ITER to fusion technology is undeniable, large gaps towards DEMO remain and there is an urgent need for continued and vigorous R&D in areas such as fusion grade materials, tritium breeding, plasma exhaust solutions, heating and current drive systems (especially in terms of efficiency), and remote handling. The integration of these technologies to build a reliable device is recognized as being, probably, the greatest challenge ahead. ITER design and construction activities have, nevertheless, yielded several important lessons for those responsible for DEMO design:

- (1) the importance of thermal transients for in-vessel component design;
- (2) strengthening of nuclear design integration and nuclear safety culture during all design phases;
- (3) implications of design changes imposed on ITER by regulatory bodies, derived from increasingly stringent nuclear safety regulations;
- (4) the criticality of a robust maintenance plan with clear provisions to access areas where contamination and activation could be higher than initially considered;
- (5) the need to address more systematically plant layout considerations, including cooling loops and auxiliary systems, and to provide adequate space to integrate all equipment, particularly in the tokamak building.

Demonstration reactors based on extrapolations from ITER

Defining appropriate plant design parameters and technical features starts with the definition of the plant requirements and involves trade-offs between the attractiveness and technical risk associated with the design options. Some of the physics assumptions (e.g., energy confinement, plasma pressure, H-mode access threshold, bootstrap current fraction, etc.), and technology assumptions (e.g., allowable divertor heat loads, structural material neutron-load limits, maximum field in the superconducting magnets, plant thermodynamic efficiency, wall-plug efficiency of Heating and Current Drive systems, etc.) play a major role in the tokamak dimensioning process. Schematic drawings of the current designs of the EU DEMO and CFETR are shown in [Figs. 4 and 5](#), respectively. The considered design parameters of these devices, along with those of JA-DEMO and K-DEMO are shown in [Table 3](#).

A major difference between the EU DEMO and CFETR ([Zhuang et al., 2019](#)) design concepts is that the CFETR design assumes steady-state operation, with a significant current-drive fraction, and hence low-density operation (which is a challenge for the divertor). The EU DEMO design is based on operation in 2-h pulses and relies on a conventional, ideally ELM-free, H-mode scenario with an emphasis on power exhaust issues. This is not yet a fixed design choice, but rather a “proxy” to be used to identify and resolve crucial design integration problems ([Federici et al., 2016; Federici et al., 2018](#)). Considerations are also given to a design capable of

Fig. 4 Schematic drawing of EU DEMO with the various component indicated. © EUROfusion.

Fig. 5 Schematic drawing of CFETR. Courtesy ASIPP, China.

a short pulse mode operation (e.g., 1 h) for nominal extrapolated performance ($H_{98} = 1.0$) and capable of moving to steady-state operation, while maintaining the same fusion power and net electrical production, when it proves possible to access plasma conditions with better confinement. However, this option requires greater confidence in physics extrapolation and highly reliable and efficient current-drive and control systems, which will require further development. In contrast, a key design consideration for CFETR is the reliance on ‘staged operation’ spanning a wide operating range (see Table 3), for the progressive development of the plasma physics, materials science and technology over the operational lifetime of the plant to achieve performance improvements through system and/or component upgrades.

Although many discussions are ongoing regarding the possibility to achieve fusion power from smaller and cheaper devices to be built on a fast timescale, there is no magic bullet to solve the integrated design problems: squeezing one element of the design

Table 3 Main machine parameters for future devices in EU, Japan, China and South Korea DEMOs.^a

Parameters	Symbol	EU DEMO (pulsed/2 h)	JA DEMO (steady-state)	CFETR (steady-state)	K-DEMO (steady-state) ^b
Major, minor radius	R_p, a (m)	9.0, 2.9	8.5, 2.42	7.2, 2.2	6.8, 2.1

inevitably exacerbates design challenges elsewhere. The design of EU DEMO is based on the present physics knowledge—i.e., the H-mode scaling, exhaust and technology—and on the experience gained in the design and construction of ITER. It is not based on an a priori decision to design a large-scale device (Federici et al., 2016).

It is essential to address integration issues in the design activity as early as possible to avoid the development of design solutions that cannot be integrated in practice. In addition, fusion is a nuclear technology and will be assessed with full scrutiny by nuclear regulators. In this context, shielding, remote handling, safety, and licensing considerations all play significant roles in the design.

System codes (see Kovari et al., 2014; Kovari et al., 2016; Reux et al., 2018) for the full DEMO power plant are being used in Europe to underpin DEMO design studies and find meaningful design points (Kemp et al., 2018). These codes are used to find solutions with a minimum major radius, which is a rough proxy for the cost of the device. Determining the available design space for DEMO has been the subject of recent European studies (Federici et al., 2016; Federici et al., 2019; Federici et al., 2017; Siccinio et al., 2019). Three overarching limitations preventing further reductions in major radius are: (1) the divertor power handling, (2) the maximum field in the conductor of the toroidal field (TF) coils and the stress in the coil casing, and (3) the access to the H-mode:

- (1) The minimum size of DEMO is currently limited by divertor exhaust power handling for a given machine size, represented in systems code terms as $P_{sep} B/qAR_0$, where P_{sep} is the power crossing the separatrix, B is the toroidal field in the plasma, q is the safety factor at the plasma edge, A is the aspect ratio, and R_0 is the machine major radius (Federici et al., 2019).
- (2) The magnet performance is a further limit on DEMO sizing: the achievable field is limited by the stresses in the mechanical structures of the coils, rather than the superconductor performance. Forces vary with B^2 , and since the coil cannot expand toroidally, it must become radially larger, rapidly limiting how small the machine can become. With an aspect ratio of 3.1, space for a breeding blanket, and stress limits of <700 MPa in the structural coil materials, targeting a field of 5T in the plasma leads to a device with $R_0 > 7$ m without considering other limitations. A growth in the coil allows higher fields representative of high-temperature superconductors (HTS), but without a corresponding increase in the stress limit, results in a larger machine (albeit, one with improved plasma confinement). To an extent, this can be overcome by excluding tritium breeding from the inboard side to reduce the plasma-magnet distance, but this seriously compromises the ability to breed fuel.

- (3) In order to access H-mode, it is assumed that the amount of power crossing a flux surface just inside the separatrix must exceed the L-H transition threshold power P_{LH} . At present, it is assumed that $P_{sep} > P_{LH}$ for DEMO, as it is likely that P_{sep} will need to be higher than P_{LH} in order to achieve sufficient controllability and confinement quality. Using the Martin scaling (Martin et al., 2008) for P_{LH} and the Greenwald scaling (Greenwald et al., 1988) for the density limit, it can be found that for a fixed P_{sep}/R_0 (i.e., divertor protection figure of merit) increasing the ratio of P_{sep}/P_{LH} can only be satisfied by reducing the magnetic field (Wenninger et al., 2015).

Allowing a variation in aspect ratio, R/a , appears to overcome some of these limits. As aspect ratio falls, elongation can be increased and a higher β_N is achievable; however the increased minor radius means that the field in the plasma is lower and the actual plasma pressure does not change much. For a given achievable field at the TF coil, there is no significant change in power density, although lower aspect ratio designs can deliver higher absolute power due to increased plasma volume (but must still respect power exhaust constraints). This increased power comes at the cost of TF coils that have a larger cross-sectional area, to accommodate the increased plasma volume.

Taking all these elements into account using more detailed models, and allowing for some conservatism, a device of $R_0 \sim 9.0$ m is required. To significantly reduce the size requires advances in plasma physics (higher energy confinement, control and diagnostics in a fusion environment, plasma scenarios that reduce the power density to the divertor target, and highly reliable techniques to mitigate the transient effects of ELMs or exploitation of ELM-free scenarios); materials and design solutions to handle higher power densities in multiple parts of the reactor during steady-state operation and transients; remote handling maintaining high availability with restricted access; and improved magnets capable of higher fields and handling the resulting structural stresses. This must be achieved while integrating nuclear safety in the design ab initio, and without jeopardizing reliability. This does not mean that the EU-DEMO is low-risk, but that the approach chosen is to minimize the risk in extrapolation.

An increased appetite for risk on fusion performance would lead to design changes, which may ultimately reduce the size of DEMO. The first is a reduction in conservatism—a more complete scientific and technical basis allows a reduction in performance margins on extrapolation and increased confidence in plasma control at high radiative fraction, plasma-facing component (PFC) surface erosion rates, or higher β_N . This may be offset by the need to operate in e.g., ELM-free regimes. It is anticipated that the ITER and DEMO research programs will improve understanding and reduce uncertainties before the DEMO design point is finalized. If the high-level goals of DEMO are relaxed (e.g., through a reduction in target electricity production or tritium self-sufficiency, or less targeted technology transfer to a fusion power plant), size savings can be achieved. Pulse length could also be shortened (to save solenoid space) or lower aspect ratio explored (this can generally achieve higher bootstrap current fraction, supporting longer pulse length without additional auxiliary current drive). In the first case, the DEMO mission is compromised and in the second, the design is based on a reduced scientific basis.

Fusion nuclear science facilities and pilot plants

Studies have been performed to evaluate what additional science and technology advances would be required to significantly reduce the scale of the devices summarized in Table 3 and/or to pursue a complementary mission to those of ITER and DEMO to make unique contributions to the world fusion development program. The Fusion Nuclear Science Facility (FNSF) (Peng et al., 2009; Menard et al., 2016; Kessel et al., 2018) aims to create a fusion-nuclear environment representative of fusion power plants to establish a materials and component operational database before proceeding to larger electricity producing devices (see Fig. 6). To be relevant to future fusion power plants, an FNSF facility and program must also utilize and advance fusion-relevant materials for radiation resistance, low activation, operating temperature range, chemical compatibility, and plasma-material interaction damage resistance.

In an FNSF program, blanket material and component development and testing leading to tritium self-sufficiency and high thermal conversion efficiency are high priority mission elements. For FNSF concepts pursued in the U.S., full poloidal Dual Coolant Lead Lithium (DCLL) blankets are pursued as the baseline blanket concept due to the potential for high operating temperature and thermal conversion efficiency. Helium Cooled Lead Lithium (HCLL) and Helium Cooled Ceramic Breeder/Pebble Bed (HCCB/PB) are considered alternate blankets to be developed in FNSF if necessary to mitigate DCLL risks in liquid metal breeder technology and the flow channel insert development (Kessel et al., 2018). Detailed 3D neutronics and tritium breeding ratio calculations are critical to assess the effects of test blanket modules and non-breeding regions (e.g., materials test modules, ports for heating and current drive systems, diagnostics, and disruption mitigation) on the viability of T self-sufficiency in FNSF.

A conventional aspect ratio ($A = 4$) and steady-state FNSF operating range has been identified (Kessel et al., 2018), and detailed analysis has been carried out for an operating point with $R = 4.8$ m, $a = 1.2$ m, $I_p = 7.9$ MA, $B_T = 7.5$ T, $\beta_N < 2.7$, $n/n_{Gr} = 0.9$, $f_{BS} = 0.52$, $q_{95} = 6.0$, $H_{98} \sim 1.0$, and $Q = 4.0$. This operating space is found to be robust to parameter variations and operates $\sim 35\%$ below the divertor exhaust power parameter limit of $P_{sep} B/q A R_0 = 9.3$ MW/m used for EU DEMO (Federici et al., 2019). At full performance the $A = 4$ FNSF generates 1.2 MW/m² average neutron wall loading, which is comparable to the EU DEMO1 value, but with a major radius approximately half that of DEMO1 (4.8 m vs. 9.1 m) and with one quarter of the fusion power (0.52 GW vs. 2.04 GW). The FNSF facility discussed here (with $A = 4$) was not designed to generate net electricity but has an equivalent engineering gain near 1 ($Q_{eng} = 0.86$) and could access $Q_{eng} > 1$ (equivalent) with increased confinement enhancement factor, i.e., $H_{98} > 1.0$. It also aims to access higher shaping (higher elongation and triangularity) and exploits a double-null divertor configuration to increase stability limits. The design uses a radial port maintenance scheme, which differs from the vertical

(2018) Overview of the fusion nuclear science facility, a credible break-in step on the path to fusion energy. *Fusion Engineering and Design* 135B: 236–270. <https://doi.org/10.1016/j.fusengdes.2017.05.081> (web archive link,).

port maintenance approach used by EU DEMO, CFETR, and several other DEMO concepts. The device maintainability and availability dependence on maintenance approach is an active area of research.

Lower aspect ratio and smaller major radius FNSF concepts based on the spherical tokamak (ST) have also been explored. An ST with copper toroidal field coils is a promising candidate for the FNSF application due to its potentially high neutron wall loading and modular configuration (Menard et al., 2016), with fusion-relevant neutron wall loadings of $\sim 1 \text{ MW/m}^2$ possible in devices as small as $R = 1 \text{ m}$, at fusion powers of 50–100 MW, and a vertical maintenance scheme enabling removal of all in-vessel fusion core elements. An ST-based FNSF with $R = 1 \text{ m}$ cannot achieve a Tritium Breeding Ratio (TBR) ≥ 1 (TBR without Be enrichment = 0.85–0.9) and would require T from external sources. Larger ST devices with $R \geq 1.7 \text{ m}$ and $P_{\text{fus}} = 150\text{--}200 \text{ MW}$ are projected to achieve $\text{TBR} \geq 1$. Potential disadvantages of the ST-based FNSF device include the lack of a central solenoid for current initiation or sustainment, neutron embrittlement of the central Cu TF magnet, hundreds of MW of resistive power dissipation in the TF magnet, and a less developed physics basis for energy confinement and non-inductive current sustainment. The NSTX Upgrade (Menard et al., 2012) and MAST Upgrade (Chapman et al., 2015) facilities and research programs are strongly aligned with addressing these ST physics issues, with NSTX-U emphasizing core transport and stability and non-inductive sustainment, and MAST-U emphasizing power exhaust mitigation using novel long-legged divertor capabilities and core-edge integration with such divertors.

While the FNSF approach emphasizes nuclear component and blanket development to demonstrate tritium self-sufficiency and steady-state plasma operation, a further related mission is that of achieving electricity break-even ($Q_{\text{eng}} \geq 1$) in a so-called “Pilot Plant” (Dean et al., 1991; Dean et al., 1992; Menard et al., 2011). Such a mission places lower priority on very high neutron fluence operation. For advanced tokamak (AT)-based Pilot Plant operation, both higher maximum field and higher effective current density within the inboard leg of the toroidal field coil was found to be a key enabling capability for achieving electricity break-even in a smaller-major-radius $R = 4 \text{ m}$, $A = 4$ tokamak (Menard et al., 2011). Toroidal field magnets using REBCO HTS tapes with very high peak on-coil magnetic field, $B_{\text{max}} = 23 \text{ T}$, have been proposed to access very high toroidal magnetic field $B_0 = 9.2 \text{ T}$ at the plasma geometric center in an $R = 3.3 \text{ m}$ compact pilot plant, “ARC”, producing 190 MW of net electric power (Sorbom et al., 2015). Compact pilot plant concepts, such as ARC (see Fig. 7) motivate the development of several potential innovations including high-field-side lower-hybrid current drive for steady-state operation, demountable superconducting TF magnets for fusion core access and maintenance, an immersion blanket using the molten-salt FLiBe as a single-phase, low-pressure, single-fluid coolant, and a long-legged tightly-baffled divertor power exhaust scheme (Wigram et al., 2019) compatible with the immersion blankets and elevated core confinement ($H_{98} = 1.8$).

Lower aspect ratio fully-non-inductive tokamak pilot plant concepts with $A = 2$, $R = 3.0 \text{ m}$, $B_T = 4 \text{ T}$, $P_{\text{fus}} = 500\text{--}550 \text{ MW}$, $Q = 10$, and $P_{\text{net}} = 50\text{--}100 \text{ MW}$ which exploit the projected very high current density of REBCO-based HTS superconducting TF magnets have also been developed (Menard et al., 2016). A proposed $A = 2$ HTS pilot plant uses full poloidal DCLL blankets, as proposed for the $A = 4$ FNSF, but has a vertical maintenance scheme similar to the EU DEMO approach. Neutronics calculations for the $A = 2$ HTS pilot plant indicate that an inboard water-cooled shield combined with a thin inboard DCLL breeding region

(2018) Conceptual design study for heat exhaust management in the ARC fusion pilot plant. *Fusion Engineering and Design* 137: 221–242. <https://doi.org/10.1016/j.fusengdes.2018.09.007> (web archive link,).

(and a thick outboard breeding blanket) can achieve $TBR > 1$, high neutron flux and fluence, and tritium and electrical self-sufficiency. Such a device may reduce the magnet mass per unit fusion power relative to higher aspect ratio configurations and may offer core stability and confinement advantages (Menard, 2019). However, at these low aspect ratios there is only room for a small central solenoid, so non-inductive current formation and/or overdrive would be needed to access the full flat-top operating current of 12–13MA. Furthermore, as is the case for the ST-based FNSF, the physics basis for higher-field low-A tokamaks with $A = 1.7$ to 2.2 has not yet been established and will need to be supported by research on NSTX-U, MAST-U, and ST-40 (Windridge, 2019).

A key question to be addressed in choosing the optimal aspect ratio for fully-non-inductive pilot plants is how energy confinement scales versus aspect ratio between spherical and more conventional tokamak aspect ratios, i.e., covering the range $A = 1.7$ to 2.4 (Menard, 2019). If high confinement and high-bootstrap fraction scenarios can be realized in near-term STs and if high-field high-current-density TF magnets can be realized (Windridge, 2019; Sorbom et al., 2015), a more modular path to fusion energy development may become feasible (Chuyanov and Gryaznevich, 2017). The UK government has also expressed interest in advancing the ST for fusion energy through the Spherical Tokamak for Energy Production (STEP) program (Wilson, 2020). STEP is proposed as a staged program to design and build the world's first compact fusion reactor based on the ST by 2040.

Prospects for stellarator-based demonstration reactors

The stellarator (Yamada, 2021) is a promising alternative to the tokamak, offering inherently steady-state operation and enhanced plasma operational reliability without severe disruptions. It is therefore being pursued internationally as a potential fusion power plant candidate. The freedom to shape a stellarator plasma in three dimensions opens up a path to resolve plasma and engineering issues by computational design rather than by relying on specific plasma regimes. Specifically, stellarators possess 40–50 degrees of freedom in shaping the magnetic field, providing a virtually infinite configuration space. However, while significant progress has been made in the physics optimization, the challenges in the area of stellarator engineering remain to be addressed. A variety of stellarator concepts exist, the most studied concepts being heliotrons and advanced stellarators (including compact designs) (MFE16, 2016).

As for tokamaks, some of the greatest challenges are in engineering and technology (e.g., 3D non-planar magnet design, heterogeneous neutron loads, divertor heat loads, 3D blanket design and segmentation, remote maintenance, etc.). Detailed studies of these issues are limited, but these aspects have gained more interest in recent years and it is expected that, with the success of devices such as W7-X and LHD, further attention will be drawn to stellarator-specific reactor-relevant engineering and technology aspects. Similar to the physics optimization, stellarator engineering offers tremendous potential to address challenges by computational design and optimization.

Design studies for a stellarator-based DEMO device are less advanced than those for tokamak-based devices, though conceptual studies of fusion reactors based on extrapolations of the most favored stellarator configurations have been developed (see Fig. 8), e.g., HELIAS 5-B (Schauer et al., 2011, 2013), extrapolated from the W7-X design (Grieger and Milch, 1993; Grieger et al., 1992), and

(Right) Reproduced with permission from Tamura H, Tanaka T, Goto T, et al. (2015) *Fusion Engineering and Design* 98–99: 1629–1633. <https://doi.org/10.1016/j.fusengdes.2015.01.025> (web archive link,).

FFHR (Sagara et al., 2012) a refinement of the heliotron concept, where extensive experimental experience has been accumulated, including more than two decades of operation of the Large Helical Device, LHD (Iiyoshi et al., 1999).

With a major radius, $R = 22$ m, HELIAS-5B has a slightly larger aspect ratio, $R/a = 12$, than that of W7-X to accommodate space for the blanket. The space between the plasma and the magnetic field coils is a limiting factor in stellarator designs and space requirements for a blanket impose a lower limit on the device size. The space between the coils is also an important factor for port-based maintenance, limiting the maximum size of the blanket segments. Therefore, optimised coil designs are under investigation that offer a higher accessibility without compromising the magnetic configuration (Gates et al., 2017). Using Nb_3Sn superconductor technology similar to ITER, which allows a field of 5–6 T on-axis, the 50 non-planar field coils are roughly the same size as the ITER toroidal field coils, allowing off-site fabrication. High-temperature-superconductors are also under consideration, but the associated quench protection and electromagnetic forces are challenging aspects that need detailed investigations.

Winding of the large helical coils, which must be prepared on-site, is a particular challenge for the FFHR design. The large poloidal field coils also require on-site assembly. Joint-winding of large-current capacity conductors employing high-temperature superconducting tapes that could be connected on site by mechanical connection offers a potential alternative. Sufficiently low joint resistance has been confirmed by a prototype conductor (Yanagi et al., 2015) and a large-scale fabrication method is under investigation. On the other hand, this concept incorporates large gaps between the helical windings, which serve as access points for port-based remote maintenance.

To provide tritium breeding in HELIAS-5B, adaptation of tokamak DEMO blanket concepts is under study. The HCPB concept (Boccaccini et al., 2021) appears favorable due to its low space requirements and very high tritium breeding ratio ($\text{TBR} = 1.38$ for HELIAS 5-B; Häussle et al., 2018). The FFHR blanket design uses a molten salt (LiF-BeF_2) self-cooled liquid tritium breeder, referred to as FLIBE (Sagara et al., 2000), though a more refined FLINABE (LiF-NaF-BeF_2) concept has been proposed to increase the acceptable temperature range, achieving a higher thermal efficiency (Sagara et al., 2017).

In HELIAS configurations, magnetic islands are naturally generated at the plasma edge. These islands are intersected by divertor plates forming the so-called ‘island divertor’. Successfully tested in Wendelstein 7-AS (McCormick et al., 2003) and the subject of further detailed investigations in W7-X (Niemann et al., 2020), this is a promising exhaust concept for a stellarator reactor. In the FFHR heliotron concept the divertor configuration also originates naturally from the helical geometry, producing a continuous helical ‘double null’-like configuration. However, plasma detachment is necessary to protect the divertor against local hotspots produced by toroidal asymmetries. Selection of a favorable magnetic configuration and/or application of resonant magnetic perturbations (RMP) are options to achieve reduced heat loads (Yanagi et al., 2019). Advanced divertor concepts using molten tin shower jets or a metal pebble flow are also under investigation (Miyazawa et al., 2017; Ohgo et al., 2019).

To bridge the physics and engineering gaps between W7-X and a HELIAS reactor, several options for an intermediate-step stellarator have been proposed (Warner et al., 2016). An intermediate device could either be: (a) a physics-focused device with significant fusion power to study burning plasmas and which can also be used as a steady-state volumetric neutron source; (b) a technology focused DEMO-like device, including a full prototype blanket, aiming to provide an integrated systems solution with a moderate amount of net electricity. The HELIAS line, features a high aspect ratio, but studies of more compact stellarator designs with two or three field periods are also ongoing (Henneberg et al., 2019). Although no such device exists, a small prototype experiment is planned in China (Isobe et al., 2019). A recent study showed that it is, in principle, possible to substantially simplify the

magnetic field coils of such a device by introducing additional permanent magnets that can generate a part of the poloidal flux and rotational transform (Helander et al., 2020).

For the FFHR concept, a step-by-step development strategy is considered focusing on system integration to overcome the engineering and technology challenges: (1) FFHR-a1, a device for demonstration of advanced engineering in a non-nuclear environment; (2) FFHR-b2, a steady-state neutron source for material qualification and testing, as well as providing an early demonstration of DT fusion in the stellarator configuration; (3) FFHR-c1, a heliotron DEMO; and (4) FFHR-d1, a full-scale power plant (Miyazawa et al., 2019). High-temperature superconductors are an option for these designs, allowing higher magnetic field and more compact devices.

Fusion materials test facilities

Introduction

Radiation damage in materials is a complex function of two competing basic phenomena (nuclear reactions and elastic collisions) for the primary damage and the specific characteristics of each material components, as well as temperature, for the later evolution of the initial effects (see Litnovsky et al., 2021 for a more detailed description of reactor materials). Elastic collisions induce atomic displacement of the ions inside the materials giving rise to point defects and nuclear reactions give rise to material activation and impurification. The relative relevance of both types of reactions is a strong function of the irradiating particles, their energy and the material composition. This complexity makes it almost impossible at present to predict the behavior of materials in a radiation environment, and systematic characterization experiments are required in the future, especially for the case of high-dose irradiation conditions (Knaster et al., 2016b).

The radiation environment of a fusion reactor is also a complex function of the reactor design and it is strongly dominated by the presence of the 14 MeV neutrons produced by fusion reactions in the areas close to the first wall. This complex environment very soon raises the need for a fusion-like neutron source focused on the development and qualification of the materials to be used in a fusion reactor. This source will mainly be used during the design phase of the fusion device (in order to define the design window of the different components) and during the licensing phase (in order to demonstrate to the licensing body that the properties of the structural materials used in the fabrication of the device are sufficiently robust under nuclear conditions, to ensure that the safety of the reactor is guaranteed). Taking this into account, the requirements for the neutron source facility can be summarized as: “the facility should be able to produce fusion-like neutrons with an intensity large enough to allow accelerated testing, up to a damage level above the expected operational lifetime in a reactor, and in an irradiation volume large and uniform enough to allow the characterization of the macroscopic properties of the materials of interest required for the engineering design of the fusion machine”. Here it is important to emphasize that the need to characterize the behavior of engineering macroscopic properties requires the use of a relatively large irradiation volume. In order to minimize this volume, the use of small sample testing techniques is nowadays strongly being developed.

The specifications of the irradiation requirements are a function of the specific fusion power plant design. In most countries with a significant fusion program, the present strategy is based on a stepped approach in which it is planned to qualify radiation effects up to the dose required by the different DEMO designs and, at a later stage, the fusion power plant needs will be addressed. So, for example, in the case of the European Roadmap and the EU-DEMO currently under development, the facility should provide a neutron flux in the high flux region of the source enabling the accumulation of fluences of 20–30 Norgett-Robinson-Torrens (NRT; Norgett et al., 1975) displacements per atom (dpa) in <2.5 years applicable to a 0.3 L irradiation volume, and fluences of 50 NRT-dpa in <3 years applicable to a 0.1 L volume.

It is important to note that several neutron sources are already available (e.g., materials test reactors), which are able to provide the required neutron flux. However, their energy characteristics are very different from those of a fusion reactor. Consequently, they can be of interest to study materials irradiation effects, but they are not useful for the qualification of the materials in a fusion reactor. For example, neutrons produced in fission reactors have a lower energy (typically up to 1–2 MeV) and the number of transmutation reactions will therefore be much smaller than in the case of neutrons produced in a fusion-like environment. On the other side, the energy spectra of the neutrons produced in spallation sources have a very high-energy tail and, as a consequence, the number and type of transmutation reactions are much higher than in the case of a fusion-like environment (Zinkle and Möslang, 2013).

Fusion-like neutron sources

In recent decades, a variety of concepts have been proposed for building a neutron facility which satisfies the testing requirements discussed above. All are based either on the production of neutrons by the interaction of D and T, or on the production of neutrons by using the interaction between a light ion (usually D) and a light target (like Li, C or Be). In the latter case, the neutron spectra produced are not exactly the same as those in a fusion reactor, but the predicted effects in the materials have been assessed to be similar. The two approaches have given rise to several different proposals, although the only one currently in a relevant engineering design phase is the so-called IFMIF-DONES (International Fusion Materials Irradiation Facility-DEMO Oriented Neutron Source) project described in more detail in section “IFMIF-DONES”.

The most obvious way to produce fusion-like neutrons is by using the D-T reaction. Usually such facilities are based on a low energy deuteron beam (a few hundreds of keV) impinging on a tritium target. The target can be solid, with tritium embedded in a solid matrix (SORGENTINA (Pillon et al., 2014), HINEG-II (Wu, 2016)) or gaseous (PNL/UW (Kulcinski et al., 2017)). The main difficulty of this approach is linked to the fact that, to obtain the required neutron flux, a high reaction rate is required. For solid targets, this is only possible with a very high power density, which is beyond present technological capabilities. Alternatively, a high number of smaller neutron sources can be applied (PNL/UW). Nevertheless, conceptual designs which have been proposed are not able to reach the required neutron fluxes.

Thus, for example, SORGENTINA is a project in which an intense 14 MeV D-T neutron source is based on continuous D and T ion beams at 40 A, 200 keV energy, impinging onto a 2 m diameter water-cooled rotating target operated at a rotational speed of about 1000 rpm. It produces up to about 10^{15} n/s (about 1×10^{13} n/cm² s over about 50 cm³ and dpa rates corresponding to 2–4 dpa per full-power year (fpy)). The facility makes use of an ion source and accelerator stages from neutral beam injectors utilized at large experimental tokamaks together with a properly scaled rotating target technology.

The PNL/UW proposal is able to produce peak damage levels of ≈ 4 –6 dpa/fpy in 15 cm³ and has a test volume of ≈ 600 cm³ covering the damage range from 1 to 6 dpa/fpy. This design is based on a quasi-commercial linear 14 MeV DT neutron source generated by injecting a 300 keV deuterium beam (of a few hundred mA intensity) into a 30 Torr tritium gas target (the pressure in the target can be tuned to optimize the irradiation parameters). A number of these small neutron sources can be arranged in a lattice configuration in which the materials to be irradiated can be located.

An interesting alternative approach is represented by the so-called “volumetric” neutron sources in which a plasma device with no energy gain ($Q < 1$), but with external heating and an external supply of D and T is used to produce 14 MeV neutrons. The Gas Dynamic Trap (GTD) (Anikeev et al., 2015) is based on a special magnetic mirror system for plasma confinement. The main advantage of this type of neutron source is that the available irradiation volume is high (typically volumes of 0.3 L at > 15 dpa/full power year; 17.5 L at 10–15 dpa/fpy; 6.9 L at 5–10 dpa/fpy and 24.7 L at < 5 dpa/fpy; Fischer et al., 2000). The main difficulties are related to the plasma regime (still not fully demonstrated), the required availability (continuous operation) and all the aspects related to the device engineering (especially tritium and remote handling management). Also some of the ST-based concepts discussed in section “Fusion nuclear science facilities and pilot plants” have been proposed as Component Test Facilities as they exhibit the proper fusion neutron spectrum.

The production of neutrons by using the interaction of D with other light ions in solid targets is utilized in FAFNIR (Surrey et al., 2014) in which a C target is used. Its performance is limited by the power handling capability of the target. Facilities in which a D-beam interacts with light ions in liquid metals constitute the IFMIF family of devices, including the IFMIF proposal (Knaster et al., 2016a), IFMIF-DONES (Ibarra et al., 2017), A-FNS (Ochiai et al., 2020) and BISOL (Liu et al., 2019). The principle is based on Li(d,xn) nuclear reactions taking place in a liquid Li target when bombarded by a deuteron beam. To obtain neutron spectra comparable to that in the first wall of a fusion power reactor, the deuteron beam is accelerated up to 40 MeV. The main difference between the various proposals is linked to the accelerator current and, as a consequence, with the corresponding irradiation performance for each.

IFMIF-DONES

The IFMIF-DONES facility will be the neutron source that can provide conditions such as anticipated for EU-DEMO. To obtain irradiation conditions comparable to those at the first wall of a fusion power reactor, the DONES Facility will produce a 125 mA deuteron beam, accelerated up to 40 MeV (5 MW beam power) and shaped to have a footprint in the range from 100 mm $\times$ 50 mm to 200 mm $\times$ 50 mm, providing an irradiation volume of up to 0.5 L that can house around 1000 small specimens irradiated to a high dose rate (over 10 dpa/fpy). The beam will impinge on a 25 mm thick liquid lithium target intersecting the beam with a transverse velocity of about 15 ms^{-1} . The Li(d,xn) stripping reactions will generate a large number of neutrons (up to 5×10^{18} n/m²s) that will interact with the material samples located immediately behind the lithium target, in the Test Modules (Ibarra et al., 2018).

The site-specific engineering design of the IFMIF-DONES facility has been underway since 2015 with the objective to be ready for construction of the facility in the early 2020's (Ibarra et al., 2019) in Granada (Spain). It is based on the IFMIF engineering design (Knaster et al., 2015) developed in the framework of the IFMIF/EVEDA (acronym that stands for Engineering Validation and Engineering Design Activities) project, but updated to take into account the validation results obtained plus modelling calculations, and simplified as much as possible in order to reduce cost. Fig. 9 shows a schematic view of the operational principles and a simplified CAD drawing of the facility.

The IFMIF/EVEDA project also developed a number of prototyping sub-projects (Knaster et al., 2013), including: (i) an Accelerator Prototype (LIPAc), assembling IFMIF components up to its first superconducting acceleration stage (9 MeV energy, 125 mA of D⁺ continuous wave current); and (ii) the EVEDA experimental Lithium Test Loop (ELTL), which integrated all elements of the IFMIF Li target facility that was used to test the long-time stability of the liquid lithium jet forming the target. Results obtained to date have not identified any significant showstoppers.

Taking all these results into account, the construction phase of IFMIF-DONES could start in the early 2020's and the facility could be operational around 10 years later. The aim is to produce first preliminary data around 2035, on time for the engineering design of EU-DEMO.

Non-nuclear development facilities

Several significant non-nuclear development facilities are currently under construction, or in planning, which are expected to deliver important complementary R&D information to the nuclear devices described in earlier sections (see Table 4). All of these devices are non-nuclear in the sense that they will not operate with a deuterium-tritium mixture.

The largest of these devices is the Japanese-European JT-60SA tokamak (Barabaschi et al., 2019). The mission of JT-60SA is to contribute to the early realization of fusion energy by addressing key physics issues for ITER and DEMO. It is a fully superconducting tokamak capable of confining high-temperature (100 million degree) deuterium plasmas, under plasma conditions equivalent to 'breakeven' (where the fusion power would be equal to the input power if the plasma were operated in D-T). It is designed to support the optimization of the plasma configurations for ITER and DEMO and has a high plasma heating and current drive power, using both positive and negative ion based neutral beams, as well as ECRH. It will typically operate for 100 s pulses once per hour, subjecting water-cooled divertors to maximum heat fluxes of 15 MW m^{-2} . The device will be able to explore fully non-inductive steady-state operation. The assembly of JT-60SA was completed in 2020 and, on entry into operation in spring 2021, it will be the world's largest operating tokamak, in succession to the Joint European Torus.

COMPASS-U in Prague (Pánek et al., 2017) is a high field, high-density tokamak, with a flexible set of poloidal field coils for generation of single-null, double-null and snowflake divertor configurations. In addition, COMPASS-U will be equipped with a closed divertor operated at high plasma and neutral density and with high optical opacity similar to future reactors. COMPASS-U will address some of the key challenges in the field of the plasma exhaust physics, reactor-relevant edge plasma physics, advanced confinement regimes, advanced magnetic configurations and materials for next-step devices. The copper coils are cooled with liquid nitrogen to allow for higher magnetic fields.

The Divertor Test Tokamak in Frascati (Albanese et al., 2019) is a high-field superconducting tokamak aimed at exploring and qualifying alternative power exhaust solutions for DEMO. The device will have the possibility to test several different magnetic divertor topologies in relevant reactor regimes. Various plasma facing materials will be tested (e.g., tungsten, liquid metals) at divertor heat fluxes in excess of 20 MW m^{-2} . The final target of the experiment is the realization of an integrated solution (bulk and edge plasma) for the power exhaust in view of DEMO. For this purpose, the DTT tokamak has edge conditions that are similar to those of DEMO in terms of dimensionless parameters.

HL-2M (Li and HL-2M Team, 2015) is a copper-conductor tokamak under construction in Chengdu, China and is dedicated to studying the critical physics and engineering issues of ITER and CFETR.

Table 4 Main parameters of the most significant non-nuclear fusion development devices.

	COMPASS-U	DTT	HL-2M	JT-60SA
Major radius (m)	0.84	2.10	1.78	2.96
Minor radius (m)	0.28	0.65	0.65	1.18
Toroidal field (T)	5.0	6.0	2.2	2.25
Plasma current (MA)	2.0	5.5	2.5	5.5
ECRH (MW)	4	20	2 (4)	7
ICRF (MW)		15		
NBH (MW)	4–5	– (10)	2 (4)	34
LHH (MW)			– (2)	
Expected operation	Late 2021	2025	Late 2020	Early 2021

Acknowledgement

The authors would like to thank S.J. Yoo, J. Li and Y. Sakamoto for providing and checking the data in **Table 3** on K-DEMO, CFETR and JA-DEMO, respectively. The work of four of the authors (AJHD, GF, AI and FW) has been carried out within the framework of the EUROfusion Consortium and has received funding from the Euratom research and training program 2014–2020 under grant agreement No 633053. The views and opinions expressed herein do not necessarily reflect those of the European Commission.

Glossary

(Magnetic) Safety factor The safety factor, q , of a given magnetic flux surface within a toroidal plasma equilibrium is most simply thought of as the “magnetic winding number,” i.e., the number of toroidal passages a (helical) magnetic field line requires within the flux surface before it closes on itself poloidally. It is related to the “rotational transform,” ι , more commonly used to describe stellarator plasmas, by $\iota = 2\pi/q$ (Galvão and Canal, 2021).

(Poloidal) divertor A toroidally continuous in-vessel structure in tokamaks which is designed to intercept (at “divertor target plates”) the peak heat fluxes flowing into the scrape-off layer and to allow extraction (i.e., by pumping) of helium produced by fusion reactions (Zohm, 2021). Stellarators use modified versions of this concept referred to as a “helical” or an “island” divertor (Yamada, 2021).

Aspect ratio The ratio R/a , where R is the torus major radius and a the (horizontal) minor radius.

Beta β Ratio of the volume averaged plasma thermal pressure, $\langle p \rangle$, to the pressure exerted by the toroidal magnetic field at the plasma center, $\beta = 2\mu_0 p B_t^2/0$. β is typically quoted in percent (Wade, 2021; Lao et al., 2021).

Beta-normalized β_N A figure of merit used to renormalize and compare the values of β achieved in different tokamak experiments, $\beta_N = \beta\%aB_t0I_p$, where a (m) is the plasma minor radius, $B_t(0)$ (T) the toroidal magnetic field at the plasma center and I_p (MA) the plasma current.

Beta-poloidal β_p Ratio of the volume averaged plasma thermal pressure, $\langle p \rangle$, to the average pressure exerted by the poloidal magnetic field at the plasma edge, $\beta_p = 2\mu_0 p B_p^2/line$, where a is the plasma minor radius and $\langle \rangle_{line}$ represents a poloidal line integral around the last closed flux surface (LCFS).

Bootstrap current A non-inductive current which arises within the plasma due to the existence of a radial pressure profile and an exchange of momentum between the trapped and passing particles.

Burning plasma Plasma in which heating is dominated by fusion products of thermonuclear reactions, i.e., α -particles in deuterium-tritium plasmas.

Central Solenoid (CS) Tokamak coil which produces magnetic flux swing generating electric field for plasma breakdown and (inductive) plasma current drive.

COE Cost of electricity (produced by a power plant).

Disruption In tokamak plasmas a sudden loss of plasma thermal energy and plasma current triggered by the growth of MHD instabilities (Lao et al., 2021).

Double-null X-point (DNX) An up-down symmetric plasma configuration in which the last closed flux surface (LCFS—see definition) is formed by a magnetic separatrix with symmetric poloidal field nulls at the top and bottom of the plasma.

Electrical gain (Q_{Elec}) $P_{e,gross}/P_{e,circ}$ —ratio of the gross electrical output power of a power plant to the recirculating electrical power required to maintain the plant operation.

Energy confinement time $\tau_E = W_{th}/P_{loss}$ Ratio of the total thermal energy of the plasma, W_{th} , to the total power lost by all mechanisms (transport, radiation, etc.), P_{loss} ; under steady-state conditions P_{loss} is equal to the total plasma heating power, i.e., the sum of the α -particle heating power resulting from DT fusion reactions, P_{α} , and the external heating power injected into the plasma, P_{heat} (Wade, 2021).

*Retired.

Full power year (FPY) Integrated power output from a power plant equivalent to 1 year of uninterrupted operation at nominal power.

Fusion gain (Q_{th}) P_{DT}/P_{heat} —ratio of the DT (thermal) fusion output power of a plasma to the input heating power from external sources.

Greenwald density n_{GW} A figure of merit used to normalize and compare the values of plasma density, n (particles per m^{-3}), achieved in different tokamak experiments, $n_{GW} = \frac{I_p}{\pi a^2}$, where n_{GW} is expressed in units of $10^{20} m^{-3}$, a (m) is the plasma minor radius and I_p (MA) the plasma current.

H-mode “High confinement mode” of operation in tokamaks, which usually requires operation above a certain level of input power (denoted the “threshold power”); also observed in stellarators.

Ideal MHD instability A magnetohydrodynamic instability which grows in an “ideal,” i.e., perfectly conducting, plasma.

ITER Major tokamak-based facility designed to produce 500 MW of fusion power using deuterium-tritium plasmas; ITER, which means “the way” in Latin, is an international project under construction in southern France.

kiloelectronvolt (keV) Temperatures, T , in thermonuclear plasmas are normally quoted in keV ($T(\text{keV}) = 10^{-3} k_B T(\text{K})/e$, with k_B the Boltzmann constant and e the electron charge): $1 \text{ keV} = 1.1605 \times 10^7 \text{ K}$

Last closed flux surface (LCFS) Magnetic flux surface within which the magnetic field lines form closed magnetic surfaces and confine the plasma. This may be created by contact with a solid “limiter” surface, or magnetically (referred to as a “magnetic separatrix”), in which case the open flux surfaces in the SOL are channeled towards a divertor target (Galvão and Canal, 2021).

L-mode “Low confinement mode” of operation in tokamaks, typically observed at low values of input heating power.

MHD Magnetohydrodynamic (relating to stability behavior of magnetically confined plasma).

Neutron wall load Power flux on the first (i.e., plasma facing) wall of a reactor due to neutrons produced by fusion reactions, typically expressed in $MW m^{-2}$.

Ohmic heating Plasma heating produced by the flow of the plasma current within the plasma.

Passing particle Plasma particle with sufficiently large component of parallel velocity to follow the helical field lines around the torus (Sarazin, 2021).

Plasma facing component (PFC) In a reactor, a cooled component facing the plasma, either on the first wall or divertor, designed to withstand heat loads in the form of electromagnetic radiation and plasma particles, and surfaced with a material (e.g., tungsten) chosen to withstand plasma bombardment.

Poloidal field coils (PF coils) Set of (toroidally oriented) coils in a tokamak which produces magnetic fields for plasma shaping and control.

RAFM Reduced-activation ferritic-martensitic: A family of steels in which the alloying elements are chosen to lower the susceptibility to radiation damage and to reduce the long-term activation under neutron irradiation.

Resistive MHD instability A magnetohydrodynamic instability whose growth is dependence on the finite resistivity of the plasma.

Scrape-off layer (SOL) In a toroidal magnetic confinement device, the layer of open magnetic field lines outside the last closed flux surface which eventually intersect (material) plasma facing surfaces.

Silicon carbide composite (SiC_f/SiC) SiC-matrix ceramic material reinforced with SiC fibers (SiC_f) that is under development for nuclear applications and is considered as a potential structural material for fusion power plants.

Single-null X-point (SNX) An up-down asymmetric plasma configuration in which the last closed flux surface (LCFS—see definition) is formed by a magnetic separatrix with a single poloidal field null, either at the top or bottom of the plasma.

Toroidal field coils (TF coils) Set of (poloidally oriented) coils in a tokamak which produces the principal component of the confining magnetic field, the toroidal field.

Trapped particle Plasma particle which is reflected from high magnetic field region on torus inboard side and circulates toroidally on torus outboard side (Sarazin, 2021).

Tritium breeding ratio (TBR) Ratio of the number of tritium atoms bred in the breeding blanket per atom of tritium burned in fusion reactions within the plasma.

Vertical displacement event (VDE) Occurs in an elongated tokamak plasma when control of the plasma vertical position is lost: the plasma moves rapidly up or down, leading to a disruption.

MCF Magnetic confinement fusion

Introduction

In view of the availability of abundant fuel resources (Campbell, 2021) and the benign safety and environmental features of fusion reactors (Taylor, 2021), numerous studies of the physics and technology characteristics of power plants based on magnetic fusion devices have been conducted during the last half century. As discussed by Donné et al. (2021), several of the major research communities engaged in the development of fusion energy have, in recent years, provided a framework for progress towards construction of fusion power plants (FPP) via the development of roadmaps delineating the major steps in the progress towards the exploitation of fusion energy for commercial electricity production. Key aspects of “burning plasma” physics and “reactor-grade” technology will be tested by the ITER project (ITER, 2002) which are then expected to be developed into prototypical concepts for an FPP via the DEMO-generation of fusion devices, which should demonstrate significant electricity generation, at the level of several hundred MW to 1 GW, e.g., (Donné et al., 2021). Following the successful operation of the DEMO-class devices, including the confirmation of the safety and environmental advantages of fusion energy and the demonstration of a viable economic potential, it is expected that commercialization of fusion energy would be undertaken and one or more types of FPP would be constructed in the period after 2050.

Initial fusion reactor concepts developed in the late 1960s and early 1970s, based on the deuterium-tritium-lithium fuel cycle (Boccaccini and Day, 2021) in toroidal magnetic confinement devices (primarily tokamaks), were large (in contemporary terms), with major radius, R , in the range 10–15 m and fusion thermal output powers of up to 6 GW. However, by 1980, progress in understanding of physics and technology aspects of tokamaks had been refined sufficiently that conceptual power plant designs had settled into the range, $R \sim 5$ –8 m, around which the majority of contemporary DEMO and power plant designs have been developed. The following discussion will, in the interests of space constraints, concentrate on the more recent developments in power plant concepts, but excellent summaries of the early progress in fusion reactor studies are provided by Conn (1981) and Braams and Stott (2002).

Conceptual studies for magnetic FPPs have encompassed a wide variety of configurations in the 70 years or so since the controlled fusion research program was launched. Nevertheless, due to the achieved levels of plasma performance, toroidal magnetic confinement configurations have largely eclipsed linear configurations across the fusion research program. Linear devices based on the magnetic mirror configuration, such the Gas Dynamic Trap (GDT), e.g., (Galvão and Canal, 2021; Ivanov and Prikhodko, 2013), and on the field reversed configuration, e.g., (Hirano et al., 2018), nevertheless, remain under investigation. The following discussion focuses on the three principal toroidal configurations, where power plant studies have reached the most advanced level of detail: the tokamak, including spherical tokamaks (ST), the stellarator and the reversed field pinch (RFP).

To develop the framework and motivation for the conceptual power plant designs discussed later, the section “**Requirements for commercial fusion power**” outlines the principal issues relating to safety and environmental considerations, operational reliability and availability, economics and timescale. In the section “**Physics issues**”, the key physics considerations influencing power plant design are discussed, while an overview of the major technology issues is presented in section “**Key technologies**.” “**Conceptual power plant designs**” discusses several examples of contemporary power plant designs based on the tokamak, stellarator and reversed field pinch configurations, and the section “**Conclusions**” develops some brief conclusions on the current status and future development of power plants.

Requirements for commercial fusion power

While the generic concepts of widespread fuel availability and the low environmental risk associated with fusion energy production have provided a long-term motivation for the development of fusion power plants, the acceptability and, indeed, viability of large-scale production of electricity from fusion power requires not only the resolution of the outstanding science and technology challenges (discussed later), but a detailed evaluation of the likely properties of fusion power plants in terms of safety and environmental impact; public acceptance; practicality of nuclear licensing, encompassing radiation confinement and waste disposal; operational reliability and availability, which must include an assessment of the achievable device component lifetime in the burning plasma nuclear environment. These issues will influence the capital cost of a power plant, which will dominate the ultimate cost of electricity (COE) and will itself feedback on both public and industrial/commercial acceptability of fusion energy. Finally, the timescale on which fusion energy can make a significant contribution to the world’s energy consumption will have a substantial impact on the likelihood of its incorporation into the resource mix, particularly in view of the current emphasis on climate change and the expansion of energy resources with reduced or zero CO₂ emission.

These issues have increasingly been integrated into FPP studies since the early 1990s, in particular through a sequence of studies in the EU (Raeder et al., 1995; Maisonnier et al. 2007; Pamela et al., 2009), the United States (Conn et al., 1990, 1998; Miller, 1998; Najmabadi et al., 1997) and Japan (JAERI, 2000; Tokimatsu et al., 2003), and the socio-economic aspects of FPP analysis, relating primarily to safety, environmental and public acceptability considerations, are now a central aspect of conceptual power plant studies. Practical experience in this area has been gained through the licensing activities for the ITER facility (Taylor et al., 2013), the first fusion facility to undergo a full nuclear licensing procedure and defined as a nuclear facility within the relevant national (French) regulatory regime. As discussed by Taylor (2021), the detailed analyses performed in support of the ITER licensing application have provided confidence that even highly unlikely accidents will have very low consequences. Although the national

nuclear regulatory frameworks can differ internationally, key elements of the safety and environmental requirements for an FPP would be:

- high confinement of radioactive materials;
- low exposure to ionizing radiation for personnel, the public and the environment.

A fundamental implication of these requirements is that there should be no need for public evacuation following even the most severe accidents. Furthermore, it is widely accepted within the fusion community that environmental impact/public acceptability will require that waste disposal on geological timescales should not be necessary, i.e., that no high level waste (HLW) should be generated and, if at all possible, waste should ultimately fall within the classification for low level waste (LLW). Both tritium contamination of in-vessel components and material activation by fusion neutrons influence the longer term waste classification. Material processing schemes exist to remove tritium from such components within plant decommissioning procedures and, as discussed by Litnovsky et al. (2021), the principal structural materials being developed for fusion power plants are designed as “low activation” materials. The aim has been to design materials which would satisfy the LLW classification and which would permit, perhaps ~100 years after decommissioning of a power plant, much of the structural material to be recycled into the construction of new FPPs. A detailed analysis of radioactive waste from EU DEMO designs (Gilbert et al., 2019) has highlighted several issues related to the composition of in-vessel materials which could enhance the residual radiation levels beyond the LLW limit on longer timescales and has proposed mitigation measures to guide future reactor designs in this area.

Operational reliability and high availability are necessary characteristics for a power plant if fusion is to find wide acceptance as a commercial source of electricity. As discussed below, analysis of the potential cost for electricity generated by an FPP shows that these factors have a significant impact on the projected COE. Key issues which affect this aspect of fusion power generation include the application of novel technologies (e.g., superconducting magnets, breeding blankets, etc.) in “industrial scale” power generation, the inherent technical complexity of the magnetically confined reactor core and “auxiliary systems” (e.g., fuel processing plant, heating and current drive systems), the challenges of sustaining operation of a burning plasma with high fusion (thermal) power gain, Q_{th} (i.e., $Q_{th} \sim 20\text{--}50$), the component lifetime in the nuclear environment, and the associated ease of maintenance. These challenges in the physics and technology areas are discussed further in the sections “Physics issues” and “Key technologies”.

Assuming that the physics and technology challenges end route to the construction of an FPP can be successfully resolved, fusion electricity must ultimately compete in the energy market with a range of other power generation technologies. A significant rise in total electricity consumption can be expected in the coming decades: the increasing global population, particularly the (increasing) fraction in the developing world, will continue to strive to achieve a higher standard of living, and the decarbonization of industry and transportation is likely to translate into a greater demand for electricity (e.g., MacKay, 2009). The energy market is currently very dynamic, as renewable resources such as wind and solar power are gradually penetrating the market in various parts of the world (particularly the developed world). Predicting the target COE in perhaps 50 years, when a fleet of FPPs could be available, therefore implies significant uncertainties. In addition, the evolution of nuclear regulatory requirements also complicates the prediction of future construction and operational costs of both fission and fusion power plants. Nevertheless, it is likely that some form of decarbonized “baseload” electricity resource will be required to complement the fluctuating electricity production associated with renewables (e.g., Wagner, 2013).

Given the current status of fusion energy research and the resultant uncertainties in the final configuration of an FPP, plus the ongoing evolution in the energy market, the specification of a definitive target for the cost of fusion electricity that would make fusion an economically attractive energy source is premature. Nevertheless, several systematic studies have been performed to examine how fusion might penetrate into the energy market and the implications for both FPP construction costs and the COE, e.g., (Miller, 1998; Tokimatsu et al., 2003; Ward et al., 2005; Lopes Cardozo et al., 2016; Takeda et al., 2018). In spite of the prevailing uncertainties, the value of determining the factors with the greatest influence on the expected COE, as a means of focusing research on optimizing these factors and on developing conceptual FPP designs which incorporate this optimization, is recognized. This analysis has shown that the capital cost of the fusion core, including the replacement of components such as the reactor first wall, blanket and divertor, which will suffer erosion or radiation damage, will dominate the COE, e.g., (Kikuchi et al., 1991; Galambos et al., 1995; Hender et al., 1996; Ward et al., 2001, 2005; Wong et al., 2001; Najmabadi et al., 2006).

To examine how the COE might vary with key parameters related to the construction and operation of an FPP, Ward et al. (2001) analyzed the predicted COE for a range of power plant designs, deriving the scaling,

$$COE \propto \left(\frac{rF}{A} \right)^{0.6} \frac{1}{\eta_{th}^{0.5}} \frac{1}{P_e^{0.4} \beta_N^{0.4} N^{0.3}}, \quad (1)$$

Where r is the discount rate, F the learning factor (i.e., cost reduction factor for a 10th of a kind plant, ranging from 0.5 to 0.8 in this study), A the FPP availability, η_{th} the thermodynamic efficiency, P_e the electrical unit size (GW), β_N the normalized β and N the normalized density ($N = n/n_{GW}$). As might be expected, factors such as β_N and N , which are essentially figures of merit for the level of plasma performance that can be achieved, figure prominently. It is notable also that the COE typically decreases with increasing unit size, although studies have, in the main, settled on a unit size with a net electrical output of 1 GW, considered to be the largest unit which would be acceptable to electricity utilities. The importance of plant availability, and therefore, component reliability and ease of maintenance, clearly also figures strongly, as was noted above. It is also not surprising that “economic” factors such as the thermodynamic efficiency, discount rate and learning factor should have a strong influence on the final COE. Fig. 1 illustrates the

Fig. 1 Comparison of scaling for predicted cost of electricity (Eurocents/kW-h) shown in Eq. (1) versus the predicted cost of electricity for the individual tokamak-based power plant concepts evaluated using the PROCESS systems code. Reprinted from Figure 2 from Ward DJ, Cook I, Lechon Y and Saez R (2005) The economic viability of fusion power. *Fusion Engineering and Design* 75–79: 1221–1227, <https://doi.org/10.1016/j.fusengdes.2005.06.160>, Reproduced with permission of publisher.

scaling shown in Eq. (1) plotted against the predicted COE for individual FPP designs derived using the PROCESS code (Hender et al., 1996) validated against ITER costings and using ITER reference plasma performance. The predicted range of €0.07–0.14/kW h is indicative of the range of uncertainties in the key parameters, both those derived from fusion physics and technology and those derived from economic conditions that may prevail when fusion electricity is finally available in the second half of the 21st century. Similar analysis derived from the ARIES power plant studies program aimed at a COE in the range \$0.065–0.08/kW h (Najmabadi et al., 1997), while the later EU Power Plant Conceptual Study (PPCS) yielded a range of designs spanning a COE of €0.05–0.9/kW h (Maisonniere et al., 2007). It should be emphasized that these costs are determined entirely by the “internal” costs of constructing, operating (including fueling), maintaining and disposing of an FPP. The “external” costs for fusion electricity, i.e., those associated with safety, health and environmental effects, are very low and would make a negligible contribution to the COE if included in this estimate, e.g., (Ward et al., 2005). This reflects the attractive safety and environmental aspects of fusion electricity generation.

Given the range of physics and technology challenges which are still the subject of ongoing R&D programs and which will need to converge via the ITER and DEMO programs to provide a reliable basis for the construction of an FPP, the absolute costs quoted above can only be considered as “ball-park” estimates based on assumptions on whether “conservative” or “advanced” physics and technology solutions will be derived from ITER and DEMO experience (and accompanying programs). Nevertheless, analysis such as that outlined here provides guidance on key issues for future R&D to take magnetic fusion from the realm of research to the practical application of electricity production, and also provides some confidence that fusion electricity can satisfy commercial boundary constraints which would complement its safety and environmental advantages and pave the way to its integration into the future energy market.

Physics issues

The international fusion research community has assembled a comprehensive physics basis for the design of the ITER device (ITER, 1999; ITPA, 2007) which provides confidence in the ITER reference physics scenario for long-pulse burning plasma operation with $Q_{th} \geq 10$. However, the analysis of plasma performance requirements for tokamak FPPs, e.g., (Kikuchi, 1990; Sheffield, 1994; Jardin et al., 2000; Campbell et al., 2006; Zohm et al., 2017) has shown that improvements in plasma performance are typically required beyond the ITER baseline operating level to ensure that electricity can be generated at economically attractive rates. Moreover, while plasma β and density appear explicitly in Eq. (1), several additional elements of fusion physics are implicit in the analysis underlying this scaling, such as the ability to handle the power exhausted from the plasma while maintaining high energy confinement quality, high β and acceptable plasma contamination, the achievement of sufficiently high current drive efficiencies to maintain steady-state operation, the exploitation of auxiliary heating and current drive systems to maintain the current profiles required for high confinement and MHD stability, and the development of plasma control capabilities to ensure an acceptable disruption frequency (typically estimated to be in the range 0.1–1 per operational year) and to suppress β -limiting instabilities.

Integrating these requirements at the reactor scale is a central challenge for the development of a viable FPP. It is not yet possible to assign a quantitative probability to the likelihood that these various issues can be satisfactorily resolved at the level that will guarantee that the conceptual designs discussed here can be realized, particularly when critical elements of the solution, the achievement of a burning plasma with significant fusion gain and the characterization of its behavior, will be demonstrated only once ITER makes the transition to DT operation in the 2030s. Nevertheless, it is possible to briefly summarize the goals of the physics research program which leads via ITER to DEMO and ultimately to an FPP. Key issues which must be addressed to finalize the physics basis for a tokamak FPP are:

- **Steady-state operation:** several of the issues discussed below derive from the aim of achieving continuous, or “steady-state,” operation of the tokamak reactor core of a power plant. Continuous production of electricity does not rely on continuous tokamak operation, but, as discussed later, pulsed operation of the tokamak within a power plant framework tends to increase the physical size of the reactor, to provide a sufficiently large central solenoid (CS) to support long-pulse operation (e.g., several hours), and creates electromagnetic and thermal stresses in the reactor components, with implications for fatigue lifetime of the reactor core. In general, therefore, the majority of tokamak FPP conceptual designs are developed around a steady-state tokamak operating scenario.
- **Plasma confinement quality:** the operational baseline for ITER operation is the so-called H-mode confinement regime (Wagner et al., 1982), which has been studied extensively in present devices and for which an energy confinement time scaling (from present devices to ITER) has been developed (ITER, 1999). The predicted energy confinement time for a given device derived from this scaling is referred to as $\tau_{E,IPB98(y,2)}$. For any FPP design study, it is conventional to define the plasma confinement quality required to reach a specified level of fusion performance by a “confinement enhancement factor,” $H_{98(y,2)} = \tau_E / \tau_{E,IPB98(y,2)}$, where τ_E is the targeted energy confinement time at the reactor operating point. It is often found that FPP plasmas need to operate with $H_{98(y,2)} > 1$, i.e., with better confinement than predicted by the H-mode confinement scaling, a condition which can be achieved under some tokamak operating conditions, often referred to as an “advanced scenario.” This impacts, among other factors discussed below, the achievable values of normalized plasma pressure, β , and fusion gain, Q_{th} .
- **Plasma pressure:** it is recognized that increasing the plasma pressure towards the limits predicted by MHD stability theory allows the development of more compact and economic power plants. Theory determines the stability limits (Lao et al., 2021) associated with pressure in terms of β , the plasma thermal pressure normalized against the magnetic field pressure. The pressure limit for a given plasma regime can be characterized in terms of a figure of merit, $\beta_N = \beta(\%) \frac{a(m)B_t(T)}{I_p(MA)}$, which, for any given plasma configuration, has an absolute limit determined by so-called “ideal” MHD instabilities. The actual value of β_N which can be achieved depends on specifics of the plasma configuration, the electromagnetic interaction with the reactor wall and whether active control measures are implemented. Since, under optimum conditions (i.e., for average ion temperatures in the range 10–20 keV—see (Wade, 2021)), the fusion power scales as $P_f \propto \beta^2 B_t^4$, efficient use of the magnetic field (a major cost driver for the reactor core) requires operation at the highest β_N for the as-designed engineering configuration. This, in turn, implies optimization of the plasma scenario to maximize the confinement and the stability limit. As an example, for “conventional” tokamak reactors (i.e., with an aspect ratio, R/a , of ~ 3) it is typically assumed that β_N in the range 4–5 can be achieved, while for the spherical tokamaks discussed later (i.e., roughly with $R/a \leq 2$) β_N values of up to ~ 8 have been assumed.
- **Plasma density:** since the fusion reaction rate, and hence fusion power, depends quadratically on the density of reacting ions, operation at the highest achievable density is desirable. In addition, as noted above, the fusion power scales as $P_f \propto n_i^2 T_i^2$, with n_i the ion density T_i and the ion temperature, so that increasing the density to hold the ion temperature around an optimum value makes efficient use of the plasma β . Operation at high plasma density also facilitates handling of exhaust power by increasing impurity radiation for fixed impurity density (see below). In tokamaks, however, an operational limit on average plasma density is observed for H-mode operation which is characterized by the Greenwald density, $n_{GW} (10^{20} \text{ m}^{-3}) = I_p (\text{MA}) / \pi a^2 (\text{m})$ (Greenwald et al., 1988). Tokamak reactor concepts tend, therefore, to be designed around this point. As discussed later, stellarator plasmas do not suffer from this constraint, but appear to exhibit a density limit determined by the balance between plasma heating power and core plasma radiation (Sudo et al., 1990), allowing greater flexibility in determining the operational density.
- **Power exhaust:** the power deposited in the plasma by α -particles, together with the power injected to heat the plasma to thermonuclear conditions initially and then to contribute to current drive for steady-state operation (see below), must be exhausted via the internal surfaces facing the plasma. These consist of the “first wall” in the main (plasma) chamber of the vacuum vessel and the “divertor,” a specialized structure, generally in the lower region of the vacuum vessel (see discussion in the section “Key technologies” and Fig. 2 later), designed to handle the highest heat fluxes, but constrained by engineering limitations to $\sim 10 \text{ MWm}^{-2}$. The majority of designs rely on (water- or helium-cooled) tungsten as the plasma facing surface (PFC), as discussed by, e.g., Litnovsky et al. (2021). To limit tungsten sputtering, the temperature of the edge plasma in contact with these surfaces must be held below approximately 20 eV (Wu and Mszanowski, 1995). Otherwise, penetration of sputtered tungsten into the core plasma would produce an unacceptable level of contamination: the core concentration of tungsten must be held below $\sim 10^{-5}$ for acceptable fusion plasma performance, e.g., (Federici et al., 2001). The solution foreseen, both to limit the peak heat flux and to reduce the plasma temperature immediately in front of the material surfaces, is a development of that proposed for ITER in which low concentrations (1–2%) of impurities such as neon or argon are introduced (“seeded”) to radiate most (perhaps 80%) of the exhaust power to the entire first wall. Recent experimental results indicating that the width of the SOL may scale inversely with the poloidal gyro-radius (and therefore inversely with the plasma current) (Eich et al., 2011) imply an increase in the expected peak heat flux in the SOL, adding a further element to the challenge of developing a satisfactory solution for handling the power exhaust in a magnetic fusion reactor.
- **Non-inductive current drive:** the plasma current in tokamaks is normally produced inductively via the flux swing in the CS. To achieve steady-state operation, the plasma current must be driven fully non-inductively by a combination of currents generated in the plasma by the heating and current drive (H&CD) systems (Dumont, 2021) and by the “bootstrap” current (Sarazin, 2021). In order to minimize the recirculating electrical power required for the H&CD systems, plasma operating scenarios are designed to minimize the contribution required from the externally driven current by maximizing the bootstrap current, in effect by maximizing the achievable value of β_N . Tokamak reactor designs with $A \sim 3$ typically aim to generate 80–90% of the plasma

Fig. 2 A 3-D cutaway view of the fusion core of the ARIES-RS power plant study. Figure 1 from Najmabadi F and the ARIES Team (1997). Overview of the ARIES-RS reversed-shear tokamak power plant study. *Fusion Engineering and Design* 38: 3–25, [https://doi.org/10.1016/S0920-3796\(97\)00110-5](https://doi.org/10.1016/S0920-3796(97)00110-5). Reproduced with permission of publisher.

current via the bootstrap process, while concepts based on the spherical tokamak aim to achieve bootstrap current fractions of at least 90%. The remaining fraction of non-inductive current must be generated with high efficiency, to minimize the injected power, and must also provide some level of current profile control to maintain MHD stability. Indeed, for tokamak FPPs at conventional aspect ratio, the achievable value of Q_{th} is more typically determined by the current drive power requirement than by the thermal power balance.

- **Disruption avoidance:** Maintaining overall stability in the plasma against a range of possible MHD instabilities is fundamental, not only to sustaining high fusion performance, but also to protecting the in-vessel structures of a tokamak reactor: some classes of MHD instability can grow to a level at which they trigger a disruption, an event in which the total thermal energy of the plasma can be lost in milliseconds, the plasma current decays in tens or hundreds of milliseconds (at the reactor scale) and beams of high energy (~ 10 MeV) electrons can be generated which carry total currents of several mega-amperes (Lao et al., 2021). Such events produce high localized heat loads on PFCs, possibly causing localized melting, and high electromagnetic forces on in-vessel structures, which must be designed to withstand the most severe cases to ensure the integrity of the in-vessel components and of the reactor vessel itself. The high energy electrons can also cause local damage to PFCs when they are lost from the residual post-disruptive plasma. Since tokamak plasmas are usually vertically elongated, disruptions are often accompanied by loss of control of the plasma vertical position, leading to a vertical displacement event (VDE), which increases the electromagnetic forces on the vessel and in-vessel structures. Avoidance, control and mitigation of disruptions is a major element of the tokamak research program and concepts for application at the reactor scale will be tested in ITER, e.g., (Lehnen et al., 2018). Nevertheless, in addition to the potential damage to the tokamak internal structures, the loss of operational time would be a severe disadvantage to a fusion reactor if disruptions remained as common as in present devices. Therefore, development of operating scenarios and control techniques to reduce the frequency of disruptions to the range 0.1–1/year will be a key element in the development of the burning plasma research program via ITER and DEMO to an FPP. While tokamaks and RFPs are subject to the large scale MHD instabilities which lead to disruptions, it is a significant advantage of the stellarator approach to fusion energy production that stellarator plasmas are free from such events.
- **Burning plasma operation:** In present magnetic confinement experiments, the heating power to the plasma is dominated either by “ohmic heating” or, more commonly, by additional heating systems injecting particle beams and radiofrequency waves. ITER is designed to be the first magnetic confinement experiment in which 3.5 MeV α -particles produced by DT fusion reactions will dominate these conventional heating methods: in a $Q_{th} = 10$ plasma, the α -heating will be twice as large as the injected heating power, a regime referred to as a “burning plasma.” Many experiments have demonstrated that energetic particle populations such as α -particles behave as expected when present at sufficiently low densities to be treated as individual particles, e.g., (Gorelenkov and Sharapov, 2021). However, in the burning plasma environment, both nonlinear physics and collective effects may start to play a role, so that the behavior of a plasma dominated by α -heating might be more complex than is currently observed. This may be particularly important in the favored steady-state regime, the so-called “advanced scenario,” where optimization of confinement and stability can involve a nonlinear interaction between the pressure and current profiles,

e.g., (Kikuchi and Azumi, 2012). Thus, establishing robust plasma scenarios to maintain high fusion gain under the plasma conditions required to sustain steady-state operation will be a major element of the ITER program, providing a basis for their further development in DEMO-class devices in preparation for an FPP.

Concepts for stellarator and RFP reactors require the resolution of the majority of the challenges outlined above, although the detailed physics relating to some aspects of plasma behavior may differ from those in tokamaks. Stellarator plasmas differ notably from tokamak plasmas in several respects, in particular, in the ease of achieving steady-state operation, the absence of plasma disruptions and access to higher density operation than in equivalent tokamaks (Yamada, 2021). Since the confining magnetic field of the stellarator is produced by the magnetic coil configuration, there is no requirement to drive current in the plasma. Once a burning plasma is established by initial injection of auxiliary heating, the plasma equilibrium can, in principle, be sustained without the need for continuous application of H&CD power to maintain the magnetic equilibrium. As discussed in the section “Conceptual power plant designs”, several concepts have been developed for stellarator FPPs based on “ignited” plasmas, i.e., plasmas sustained purely by α -heating after an initial phase of auxiliary heating designed to reach thermonuclear conditions. The absence of a plasma current also frees stellarators from the MHD instabilities associated with the current, in particular disruptions. The nature of the density limit also allows more flexibility in the choice of operating point for stellarator plasmas. On the other hand, control of the 3-D stellarator equilibrium, to preserve closed magnetic surfaces across the entire plasma as the plasma β increases and to minimize losses of high-energy α -particles, is a significant challenge for high fusion gain plasmas.

A key advantage of RFP plasmas (Zuin, 2021) is operation at lower magnetic fields than is required by tokamak plasmas, therefore allowing exploitation of plasmas with substantially higher values of β , opening the path towards a fairly compact reactor core (see the section “Reversed field pinch concepts”). However, the existence of large-scale MHD modes in RFP plasmas, which currently limits the energy confinement to values which are perhaps two orders of magnitude lower than those in equivalent scale tokamak plasmas, represents a major challenge in progressing to reactor-relevant experiments. The contemporary RFP research program is therefore focused on the development of techniques for active control of the MHD modes and of the plasma current profile to suppress the mode amplitude and enhance the energy confinement.

Key technologies

While ITER will provide a significant testing ground for most key technologies required for DEMO and FPPs, it is recognized that, in some areas, significant further developments will be required to satisfy the increased demands of operation in the burning plasma environment of a power plant core, with, e.g., substantially higher neutron wall loads and plasma exhaust power, while maintaining the required electrical output with high availability. Fig. 2 illustrates a cutaway view of the (tokamak) fusion core of the ARIES-RS conceptual design (Najmabadi and The ARIES Team, 1997), which, in overall structural terms, is prototypical of toroidal FPP designs. A stellarator would have an inherently more complex 3-D geometry (whereas the tokamak and RFP are essentially toroidally symmetric), would lack a CS and would have a set of either modular or helical magnetic field coils in place of the TF/PF coil combination of the tokamak. Nevertheless, the overall structure, involving PFCs (first wall and divertor), breeding blanket, shielding structure, vacuum vessel, superconducting coils, thermal shield and cryostat, with access ports for operational (H&CD, Diagnostics) and maintenance systems, would follow the same pattern. An essential consideration that must be integrated into the design is the degree of shielding required to protect personnel and certain reactor components against the fusion neutrons: the breeder modules should provide a shielding factor of $\sim 10^2$ (in terms of neutrons m^{-2}) while the dedicated shield structure between the breeder modules and the vacuum vessel must further reduce the neutron flux by a factor of at least 10^4 . A total neutron attenuation factor of 10^6 should ensure survival of the superconducting magnets against radiation damage for the plant lifetime, but a radiological shield (typically concrete) surrounding the fusion core contributes a further attenuation factor of $\sim 10^2$ for personnel protection, see, e.g., (Najmabadi, 1999).

One detail in which the ARIES-RS configuration differs from many current devices and ITER is the use of both upper and lower divertors. This “double null X-point” (DNX) configuration, as opposed to the “single null X-point” (SNX) configuration of most major contemporary devices, appears in many FPP design concepts due to the use of highly shaped plasmas (i.e., high plasma elongation and triangularity), for which the β -limit, and therefore achievable fusion power density, is increased. The high shaping leads naturally to the development of up-down symmetric plasma configurations and favors the simultaneous formation of divertor magnetic configurations at the top and bottom of the plasma chamber.

Magnet systems are critical components in determining the overall performance of the fusion reactor and are also a significant factor in the cost of the FPP core. Numerous studies have been developed around the current “standard” low temperature superconductors (LTS) foreseen in ITER (Mitchell and Devred, 2017), with Nb_3Sn used in the TF and CS, where maximum values of magnetic field in the range 12–16 Tesla (T) are required, while NbTi is used in the PF coils, which operate at lower magnetic fields. The lack of space and shielding in the central core of spherical tokamaks, however, has hitherto prevented the use of LTS in the TS systems of conceptual FPPs based on the ST concept and therefore the use of water-cooled copper operating at room temperature, or helium-cooled aluminium operating at 30 K has been proposed, e.g., (Voss et al., 2002; Najmabadi et al., 2003). More recent studies, with somewhat higher aspect ratios of ~ 2 , have developed FPP concepts at higher toroidal field using LTS, e.g., Nb_3Al (Gi et al., 2015). Conceptual stellarator FPPs generally aim to limit the maximum field to ~ 12 T, allowing the use of NbTi , but, as discussed later, some design studies have targeted higher field values, in the range 14–16 T, and therefore make use of Nb_3Sn .

In RFPs, the significantly lower TF requirements allow NbTi to be applied, although in several cases a significant fraction (or all) of the magnet system operates at normal temperatures.

LTS is now considered as a mature technology for fusion devices, with several current tokamaks and stellarators in routine operation with both Nb₃Sn and NbTi magnet systems (Zohm, 2021; Yamada, 2021) and ITER's reactor-scale magnets under construction. Nevertheless, FPP designs would benefit from high temperature superconductors (HTS): operation in the region of 20 K (required to allow the target values of current density and magnetic field to be achieved), rather than at the 4.2 K typical for LTS, would avoid the need for a liquid helium cryogenic circuit and lower the cryogenic power requirements by a factor of several, reducing the recirculating electrical power fraction; in addition, the higher magnetic fields which can be achieved, in principle, with HTS would allow a reduction in the size of the FPP for a given power output, e.g., (Zohm, 2019). Although HTS have been used, e.g., in the current feeds for the ITER magnet system, and FPP concepts such as A-SSTR2 (Nishio et al., 2001) and ARIES-AT (Najmabadi et al., 2006) have been developed around the use of HTS such as Bi-Ag and YBCO (yttrium-bismuth-copper oxide) respectively, no experimental fusion device or model coil with comparable performance requirements has been demonstrated. More recently, the development of REBCO (rare-earth-barium-copper oxide) tape with the potential for high current density and magnetic field has stimulated the conceptual development of proposals towards more compact tokamak reactors with HTS magnet systems (Sorbon et al., 2015; Sykes et al., 2018). Nevertheless, substantial R&D programs will be required to develop the performance level required of HTS magnets for FPPs based on this technology and to reduce the superconductor material cost, which is an order of magnitude greater than that for the LTS material currently in use (Bruzzone et al., 2018).

As discussed by Litnovsky et al. (2021) (see also (Stork and Zinkle, 2017) and related papers), reactor materials are subject to very significant performance demands, in terms of heat loads, neutron exposure and operational temperature range. Plasma facing materials on the first wall and divertor targets are subject to high stationary heat loads (ranging from $\sim 1 \text{ MWm}^{-2}$ in the first wall region to $\sim 10 \text{ MWm}^{-2}$, or beyond, at the divertor target plates), bombardment by plasma particles (causing sputtering and erosion of the surface), and neutron fluxes which correspond to power fluxes of several MWm^{-2} (the precise value depends on the assumed plasma fusion performance), leading to a range of radiation-induced effects and transmutation reactions with potential formation of helium bubbles. In addition, plasma MHD instabilities may give rise to significant electromagnetic loads, as well as transient heat loads which can produce localized melting, though, as noted previously, the frequency of such events in a reactor must be limited to < 1 per year.

There is no ideal solution to this problem, but the majority of reactor designs have selected tungsten or tungsten composites for the divertor targets, the regions exposed to the highest heat fluxes and plasma particle fluxes. Tungsten is also often chosen for the first wall. Alternatively, on the assumption that means of controlling the plasma-wall interaction will be available at the time of FPP construction, the wall material is simply taken to be the same as the structural material for the breeding blanket. Liquid metals, such as lithium and tin, are under investigation as possible solutions to the challenges of providing resilient plasma facing components for fusion reactors, but R&D in present programs is at an early stage (see, e.g., (Mazzitelli et al., 2011; Ono et al., 2017)) and very few conceptual FPPs have been proposed which exploit liquid metals as the plasma facing materials.

Structural materials for in-vessel components, in particular the breeding blanket, shielding structure and divertor, are exposed to many of the same issues as plasma facing components, although, in general, the plasma facing surface is typically considered distinct and designed to handle the specific issues associated with heat and particle fluxes from the plasma. Nevertheless, these structures must absorb the fusion energy produced by the plasma and provide it to the heat exchangers at a sufficiently high temperature to allow a high thermal conversion efficiency in the generation of electricity. The most favored, and most highly developed, materials for this application are the reduced-activation ferritic-martensitic steels (RAFM), e.g., (Tanigawa et al., 2017), which are capable of satisfying the FPP operational specifications, as well as meeting safety and environmental requirements (Taylor, 2021). However, the limited operational temperature range of the present generation of these steels, typically 350–550 °C, constrains the achievable thermal conversion efficiency, though proposals have been advanced to raise the coolant outlet temperature by inserting thermal insulation between the breeder and the ferritic steel structure, allowing a coolant outlet temperature of 700 °C (Najmabadi et al., 2003).

Research is underway to develop a further generation of advanced RAFM steels and also oxygen dispersion strengthened (ODS) steels which would have the potential to offer higher thermodynamic efficiency, superior resistance to neutron damage, improvements in reactor operational lifetime and reliability, and reduced construction costs (Zinkle et al., 2017). Alternatives to the RAFM approach have also been investigated as possible FPP solutions: the use of both vanadium alloy and silicon carbide composites (SiC/SiC) has been developed within several FPP concepts, including the ARIES power plant study program, e.g., (Najmabadi et al., 1997). When combined with appropriate breeding and cooling materials, such approaches could allow significantly higher thermal conversion efficiencies to be achieved while retaining attractive safety and environmental properties.

Considerable R&D is required to fully characterize the impact of neutron irradiation levels expected in an FPP and to demonstrate that changes in properties such as thermal conductivity and structural integrity and strength are acceptable, e.g., (Van der Schaaf et al., 2006). The achievable lifetime of near-plasma components will be a key issue: FPP first wall neutron loads are typically in the range $1\text{--}6 \text{ MWm}^{-2}$, i.e., $0.44\text{--}2.7 \times 10^{18} \text{ neutrons m}^{-2} \text{ s}^{-1}$, and the annual neutron fluence of $1\text{--}6 \text{ MW year m}^{-2}$ corresponds (for steels) to an annual displacement per lattice atom (dpa) of $10\text{--}60 \text{ dpa}$ for plasma facing surfaces. The tolerable irradiation lifetime of structural materials is typically assumed to lie in the range $100\text{--}150 \text{ dpa}$, implying a requirement to exchange near-plasma components (i.e., the breeding blanket, including the first wall, and divertor) every 3–10 years, a period which is significantly shorter than the assumed lifetime of the power plant. This has an impact on both the lifetime costs and availability of an FPP.

The key issue of tritium breeding technology is intimately connected with the choice of structural materials, the design of the structures facing the plasma and the blanket coolant scheme. Boccaccini and Day (2021) discuss the present considerations in

relation to reactor breeder blankets and the R&D program via ITER designed to identify the most promising options—despite the critical nature of tritium breeding from lithium in the fuel economy of an FPP and the implications for fusion as a viable source of large-scale energy production, ITER will be the first opportunity to test breeding module concepts as an integrated technology. Abdou et al. (2021) have recently completed a detailed analysis of the tritium breeding ratio (TBR) required in a fusion reactor, indicating that a target value in the range $1.05 \leq \text{TBR} \leq 1.15$ is likely to be required, but that extensive further physics and technology R&D will be necessary to ensure that such values are attainable in the reactor environment. Additional challenges will need to be addressed to achieve such values of TBR in the spherical tokamak environment, where the breeding blanket is limited to the outboard side of the torus, and in stellarator FPPs, where the limited clearance between the plasma and superconducting coils prevents a uniform coverage of tritium breeding modules, as discussed in the section “Conceptual power plant designs”.

Within the framework of the breeding blanket R&D, the coolant scheme is a major consideration, since it is closely coupled to the design of the breeding blanket, has an impact on the extraction of high grade heat for electricity generation, i.e., the thermal conversion efficiency, affects the recirculating electrical power fraction (with helium particularly demanding in this respect) and also has safety implications, e.g., via the consequences of water leaks into the vacuum vessel, due to the reactivity of liquid metals with steam or air, or permeation of tritium into water or gaseous coolants. Assumptions related to integrated breeder blanket designs which satisfy the requirements on TBR while allowing for efficient heat extraction at high temperature consistent with the operating temperature limits of structural and breeder materials are therefore a significant element in the analysis of overall FPP performance.

Extension of H&CD technology to the reactor scale will be an essential element of the R&D activity to ensure that the required level of plasma fusion performance can be achieved and sustained in steady-state tokamak FPPs, e.g., (Inoue et al., 2021). Developments required for H&CD applications in ITER will advance the technologies in this area towards meeting the requirements for DEMO and FPPs. Nevertheless, substantial R&D will be necessary to ensure that the key H&CD systems considered viable in the reactor environment will achieve the required level of electrical conversion efficiency while providing the specified power continuously for periods, say, of order a year, implying significant progress in system reliability. Since radiofrequency sources can be sited remotely from the fusion core, RF system performance will be less sensitive than that of neutral beam injection systems to the high radiation environment of the FPP burning plasma, where the first wall neutron flux will be a factor of several above that in ITER and the annual neutron fluence will be approximately two orders of magnitude greater. The quasi-optical propagation of radiowaves in the electron cyclotron frequency range ($\sim 100\text{--}200$ GHz) will be particularly advantageous, while the close coupling to the plasma required by ion cyclotron radiofrequency (ICRF) H&CD (operating in the frequency range $\sim 100\text{--}200$ MHz) will present challenges in ICRF antenna design.

Fig. 3 provides an illustration of the impact of assumptions on plasma performance and reactor technology on the scale of tokamak FPPs. The figure shows the poloidal cross-section of a series of design concepts developed within the EU's fusion power plant conceptual study (PPCS) program, with the ITER cross-section for comparison (Maisonnier et al., 2007). The largest of the devices, models A, AB and B, assume somewhat better (by $\sim 30\%$) plasma performance parameters than would be derived from

Fig. 3 Variation of poloidal plasma cross-sections of the conceptual power plant concepts developed in the EU PPCS studies, with the ITER plasma cross-section shown for comparison: R is the major radius coordinate and Z the vertical height. As the physics and technology assumptions were made more ambitious, the sequence of devices varied from A/AB to D (Note that device B has been slightly increased in size to renormalize the net electrical output to 1.5 GW, providing a common basis for the scale comparison). Figure 1 from Maisonnier D, Campbell D, Cook I et al. (2007) Power plant conceptual studies in Europe. *Nuclear Fusion* 47: 1524–1532, <https://doi.org/10.1088/0029-5515/47/11/014>. Reproduced with permission of copyright holder (IAEA).

the ITER Physics Basis (ITER, 1999). However, the “conventional” plasma regime assumed limits the plasma β and the bootstrap current fraction, requiring a high level of auxiliary heating to achieve 100% non-inductive current drive. The use of “conventional” blanket technology, i.e., RAFM structural material, which limits the coolant temperature and therefore the thermal conversion efficiency, together with the significant fraction of recirculating electrical power, necessitates a high fusion power production (5 GW in the case of model A) to provide a net electrical output of 1.5 GW.

The large dimensions of these devices are also driven by constraints on the divertor power loading—indeed, there is a complex interplay between plasma confinement, H&CD power requirements and acceptable divertor heat fluxes. If more ambitious targets are allowed for fusion plasma performance, i.e., an “advanced” plasma scenario, and β is allowed to rise accordingly, the bootstrap current contribution increases, reducing the auxiliary heating requirement. In addition, models C and D make use of more advanced blanket concepts, either a He-cooled RAFM structure with SiC_f/SiC insulators and an LiPb breeder (model C), or an LiPb self-cooled breeder blanket with a SiC_f/SiC structure. Both approaches increase the assumed thermal conversion efficiency and reduce the electrical pumping power. The “advanced” technology assumptions of the two smaller models include an increase in the electrical efficiency of the H&CD systems (0.7 vs. 0.6 for the larger devices), also contributing to a reduction in the recirculating electrical power fraction. Not surprisingly, the projected COE of these devices decreases by almost a factor of two between model A and model D.

Conceptual power plant designs

Tokamak/Spherical Tokamak concepts

Detailed studies of concepts for tokamak fusion power plants have been carried out internationally in recent decades. The US ARIES program has developed a series of concepts, comparing pulsed and steady-state tokamak designs, analyzing also the spherical tokamak concept and, as discussed later, stellarator and reversed field pinch configurations. FPPs based on both the tokamak and ST concepts have also been developed by the EU and Japanese fusion programs. Table 1 provides a list of principal parameters of several tokamak and spherical tokamak FPP concepts developed during this period.

The PULSAR-I concept (Bathke et al., 1994) illustrates an FPP developed around a tokamak core having a pulse length of ~ 2.5 h. Although an earlier proposal than the steady-state concepts discussed below, it is nevertheless relevant, since some contemporary options for a DEMO, e.g., (Federici et al., 2017) propose a pulsed device as a conservative approach, potentially allowing more rapid construction of DEMO as soon as ITER results provide an adequate physics and technology basis. The need to limit cyclic fatigue in the TF coil, which then constrains the maximum value of toroidal field at the coil inner leg, is a significant factor in determining the large major radius of the PULSAR-I device. The resultant scale of this device might be more typical of a first generation FPP, since the physics assumptions incorporated in the design are more characteristic of those underlying ITER, rather than of the more advanced assumptions, in terms of plasma confinement and β_N , incorporated in the steady-state FPPs listed in the table. The scale and more conservative technology applied in the design of the PPCS-A, PPCS-AB and PPCS-B concepts illustrated in Fig. 3 could also be considered to be in this category, though they are designed around steady-state tokamak operation. On the other hand, the use of SiC_f/SiC as a first wall, blanket and shield material in PULSAR-I is likely more appropriate to later FPP generations.

A noteworthy aspect of the PULSAR-I physics operation is that it is developed around “ignited” operation, i.e., with no additional H&CD after an initial application to heat the plasma to the state where fusion reactions take over and fully maintain the burn point. In contrast, the majority of tokamak FPP designs foresee the tokamak plasma operating as a “power amplifier” with a typical thermal fusion gain in the range 20–50. To address the issue of continuous electricity production, essential for a “baseload” power plant, the design makes use of the thermal storage capacity of the neutron shield to supply thermal power to the heat exchangers for a period of 200 s while the plasma is terminated, the tokamak CS “recharged” and the plasma reheated to ignition. Nevertheless, as a result of the design elements associated with pulsed operation, the projected COE associated with PULSAR-I was found to be $\sim 30\%$ higher than for equivalent FPP concepts developed around steady-state tokamak operation.

The PPCS-C (Maisonier et al., 2007), ARIES-AT (Najmabadi et al., 2006) and A-SSTR2 (Nishio et al., 2001) devices represent designs based around “conventional,” i.e., moderate to high, aspect ratios. Advanced plasma regimes, to allow access to high values of β_N , were combined with assumptions on future technological developments to produce moderately compact devices operating in steady-state. There are, nevertheless, significant differences in the technology exploited. For example, in PPCS-C, the TF magnets used the well-established Nb₃Sn superconducting strand, while the A-SSTR2 designers proposed to fabricate the TF windings from an HTS strand, Bi-Ag alloy, operating at 20 K and allowing a substantially higher field (23 T) at the TF coil inner leg than Nb₃Sn. The design of the ARIES-AT TF magnet was developed around the YBCO HTS operating at 77 K, but at a moderate value of TF field, since the concept incorporated advanced physics assumptions, including (self-consistently) operation at a particularly high value of β_N . In addition, while the PPCS-C design assumed that the principal in-vessel structures were fabricated from a reduced activation ferritic-martensitic steel, EUROFER, which has been the subject of extensive R&D, the ARIES-AT and A-SSTR2 designs made use of SiC_f/SiC, allowing a higher blanket coolant temperature and therefore higher thermal efficiency. A further unusual feature of the A-SSTR2 design is the elimination of the central solenoid, so that the plasma current ramp-up would be performed fully non-inductively—this represents the end-point of conceptual developments in which the central solenoid is “slimmed” to reduce the radial build of the tokamak, requiring an increasing non-inductive contribution to the current ramp-up. Simulations of the current ramp-up for A-SSTR2 showed that the sequential application of RF waves and neutral beam injection could allow the operating current of 12 MA to be achieved in ~ 22 h.

Table 1 Principal parameters of several tokamak and spherical tokamak power plant studies.

Parameter	<i>PULSAR-I</i> (Bathke et al., 1994)	<i>PPCS-C</i> (Maisonnier et al., 2007)	<i>ARIES-AT</i> (Najmabadi et al., 2006)	<i>A-SSTR2</i> (Nishio et al., 2001)	<i>STPP</i> (Voss et al., 2002)	<i>ARIES-ST</i> (Najmabadi et al., 2003)
Toroidal field (axis) (T)	6.7	6.0	5.8	11	1.8	2.1

^aIn plasmas with a magnetic separatrix, it is common to characterize the plasma equilibrium by quoting the elongation κ , triangularity, δ , and safety factor, q , at the magnetic flux surface which encompasses 95% of the poloidal magnetic flux in the plasma (i.e., just inside, but close to, the separatrix).

^bTotal thermal power exceeds the fusion power due to the exothermic tritium-breeding reactions.

^cODS-s: oxygen dispersion strengthened (reduced activation) steel.

^dRAFM: reduced-activation ferritic-martensitic steel.

^eThe eutectic form referred to as PbLi varies in composition across the literature: in the EU literature, the composition Li_{15.8}Pb_{84.2} is favoured (also referred to as Pb-15.8% at Li), while in the US literature the composition Li₁₇Pb₈₃ is favoured.

^fLi₂O and Li-ceramic (e.g., Li₂TiO₃) breeder materials generally require a neutron multiplier (e.g., Be).

^gOutlet temperature of coolant—temperature of breeder material may be higher.

As discussed in the section “Requirements for commercial fusion power”, a key issue critical to the credibility of fusion as a major energy resource, is the frequency with which PFCs and breeding blankets must be replaced (and the duration of the associated “maintenance” activity), since this is assumed to be the determining factor in the power plant availability. As well as the impact on the annual operating costs of the FPP, this also influences the volume of waste for disposal. It would be preferable to match the PFC and blanket replacement cycles. However, this is not always possible. In the PPCS-C design, for example, the low neutron wall loading and the use of RAFM steel for the blanket structure allowed a 5-year interval between blanket replacements (assuming an irradiation lifetime of ~ 150 dpa), while the divertor PFC lifetime was estimated to be 2 years. In the ARIES-AT concept, it was assumed that the lifetime of the blanket structure was limited by 3% burnup of SiC, leading to an estimated 4-year replacement cycle (4 full power years (FPY), to be precise). It was also assumed that the divertor PFC replacement cycle could be matched to this. The very high neutron wall load in the A-SSTR2 design limited the lifetime of the blanket to 2 FPY, and it was assumed that the blanket could be replaced within 2 months on a 2-year cycle. Clearly an important aspect of sustaining high availability is the capability of replacing major in-vessel components rapidly on a regular cycle and this is therefore a significant consideration in the design of the fusion power core and of the maintenance (remote handling) technology.

The scale of the devices listed in Table 1, in terms of the electrical power output, is large, typically of order 1 GWe or greater, and this reflects the relationship between COE and unit size given in Eq. (1). The combination of advanced physics and technology in the ARIES-AT and A-SSTR2 concepts implies that they might be considered as long-term developments of the tokamak concept

towards an optimized FPP, whereas the PPCS-C design, relying on near-term technological readiness and physics assumptions which are less ambitious than those of ARIES-ST or A-SSTR2, might be achievable at an earlier phase of FPP implementation.

The ST approach to fusion energy production aims to develop more compact, and possibly cheaper, solutions for the fusion power core. Physics analysis also inspires this approach since both experimental results and theoretical studies, e.g., (Peng and Strickler, 1986; Menard et al., 2016; Harrison et al., 2019; Kaye et al., 2019) indicate that low aspect ratio favors both improved confinement and enhanced MHD stability in comparison with conventional tokamaks (aspect ratio $\sim 3\text{--}4$). Experimental progress in STs is more limited than in the conventional approach, but the potential physics and cost advantages have motivated a study of FPP concepts at low aspect ratio, as illustrated by the STPP (Voss et al., 2002) and ARIES-ST (Najmabadi et al., 2003) designs listed in Table 1. As is evident from the physics parameters listed in the table, the fusion core of an ST power plant would be expected to operate at substantially higher values of β and β_N than conventional tokamak designs, but at values that are, nevertheless, plausible on the basis of the relevant experimental and theoretical background.

An important consequence of operation at such high values of β_N is that the pressure driven currents in the plasma (primarily bootstrap current, but other physics processes also contribute) generate 95–99% of the total plasma current, implying that only a small fraction of the total current must be driven by the auxiliary heating systems to support steady-state operation. This would resolve a key challenge of steady-state operation in the ST configuration: due to the large fraction of trapped particles typical of low aspect ratio plasmas, the achievable current drive efficiency with auxiliary heating systems is significantly lower than in plasmas at conventional aspect ratio. A viable scenario for plasma start-up and (predominantly non-inductive) current ramp-up must also be developed for such low aspect ratio ST FPP concepts, since the limited space on the inboard side of the plasma does not allow the inclusion of a central solenoid. Experimental R&D is underway to demonstrate this capability, e.g., (Bongard et al., 2019; Ono et al., 2019). Satisfactory dissipation of the plasma exhaust power flowing to the divertors during high fusion power operation at low aspect ratio must also be addressed. Redistribution of the exhaust power via impurity radiation, as is foreseen for conventional tokamaks, will probably form the basis of the solution, but maintaining the required radiated power fraction while sustaining the necessary level of fusion performance will be even more challenging. Therefore, novel magnetic configurations for the divertor geometry to mitigate divertor heat loads in the ST configuration are under study, e.g., (Harrison et al., 2019).

Many elements of the technology used in these concepts are shared with the conventional tokamak designs. However, as indicated in the section “Key technologies”, an important difference is that the low aspect ratio imposes space constraints on the inboard side of the plasma, limiting the achievable neutron shielding factor and preventing the use of magnets fabricated from LTS. The water-cooled copper magnets in the TF system then make a significant demand on recirculating electrical power and this can be seen in the table. As noted in the section “Key technologies”, use of a somewhat higher aspect ratio, ~ 2 , would allow the use of LTS and, if HTS technology such as REBCO eventually confirms its potential, this could have a significant impact on the design of FPPs with an ST fusion core (Sykes et al., 2018). The space constraints on the inboard side of the plasma restrict the use of a breeding blanket to the outboard side, but nuclear analysis of the two design concepts shown in the table indicated that, with neutron multiplication and adequate ${}^6\text{Li}$ enrichment, an acceptable TBR of ~ 1.1 could be achieved. The high neutron wall loads, $3.5\text{--}4\text{ MWm}^{-2}$, imply a short replacement time for the blankets, and indeed much of the structure in close proximity to the plasma: for STPP the blanket lifetime was estimated as ~ 2 FPY, while the ARIES-ST designers considered a lifetime of almost 3 FPY possible.

Stellarator concepts

Although stellarator power plant concepts were studied during the early decades of magnetic fusion research, the rapid development of plasma performance in tokamaks led to a neglect of the stellarator line for several decades. Stimulated by conceptual improvements in the stellarator magnetic configuration, which were accompanied by promising developments in plasma performance during the 1980s and 1990s, the recognition that the potential for intrinsically steady-state plasma operation and disruption-free plasmas represented significant advantages for a power plant reinvigorated physics and engineering analysis of the stellarator as the core of an FPP. The term “stellarator” encompasses several subtly different magnetic configurations (Yamada, 2021). The examples of stellarator FPP concepts listed in Table 2, therefore, illustrate options developed around the three most promising configurations: the torsatron/heliotron (FFHR-d1A), the helias (HSR4/18, HSR5/22) and the quasi-axisymmetric stellarator or QAS (ARIES-CS). The relative merits and challenges associated with each of these configurations are detailed by Yamada (2021).

A key challenge in the design of stellarator FPPs is that the higher order components of the confining magnetic field, which is produced entirely by currents in coils external to the plasma, decay rapidly with distance from the coils to the plasma. This implies that the radial space available for breeding and for shielding of the coils is limited. This is particularly problematic on the inboard side of the plasma, due to the helical shape of the magnetic flux surfaces. Since it is nevertheless necessary to provide sufficient radial space (ideally $\sim 1.3\text{ m}$) for the breeding and shielding blankets between the plasma and coils, stellarator reactor designs tend to be rather larger in scale than tokamaks with equivalent net electrical power output. Of course, the plasma scale required to achieve significant fusion gain—the stellarator concepts listed in the table are all designed to operate in “ignited” mode, i.e., with infinite gain—and fusion power production must be integrated into this engineering constraint. In addition, the complex shape of the coils required to produce the helical configuration can generate large electromagnetic forces on the coil system, requiring significant mechanical restraint within a limited space. Finally, it should be noted that the need to facilitate maintenance access to in-vessel components within the helical configuration leads to a significant increase in the complexity of the fusion core components compared to those in tokamak reactor concepts. The FPP studies illustrated in the table have exploited advances in the conceptual design of helical systems to address these problems and to allow practical solutions to the reactor constraints.

The Force-Free Helical Reactor, FFHR-d1A (Sagara et al., 2017), is a member of a family of similar reactor-scale devices which has been developed from the heliotron configuration of the Large Helical Device (LHD) (Iiyoshi et al., 1999; Yamada, 2021), in which two helical coils, carrying currents in the same direction, encircle the toroidal plasma. The magnetic equilibrium also requires a small number (four in the case of FFHR-d1A) of poloidal field coils to complete the equilibrium configuration. The resultant magnetic equilibrium naturally generates two helical divertors on either side of the plasma. The “basic” design option of this device was based on ITER technology wherever possible, e.g., the superconducting coils are fabricated from Nb₃Sn, the breeding blanket concept was based on the water-cooled ceramic breeder concept under development by Japan for testing in ITER and the divertor targets were assumed to exploit the water-cooled tungsten technology being developed for ITER. A technologically “challenging” option making use of HTS (e.g., REBCO) magnets, a molten salt (FLiNaBe/metal powder mixture) breeding blanket and a liquid metal (Sn) divertor target was also studied. A notable feature of this and the other stellarator concepts listed is that the average neutron wall loading is modest compared to the majority of tokamak concepts discussed previously, implying a significantly longer period (possibly ~10 years) between blanket replacements than in the tokamak reactors. The volume of blanket to be replaced is, however, larger. Nevertheless, as in tokamaks, regular replacement of high power handling PFCs would be required on a shorter timescale than the blanket replacement.

The Helias (helical advanced stellarator) reactor concepts, HSR4/18 and HSR5/22 (Beidler et al., 2001; Wobig and Wagner, 2005), are developments of the W7-X optimized advanced stellarator (Grieger et al., 1992; Yamada, 2021). HSR5/22 is an analogue of the W7-X device, with five toroidal periods, while HSR4/18, has four toroidal periods, resulting in a more compact device. In addition to the physics optimization designed to minimize several limitations of the conventional stellarator,

a particularly attractive feature of this concept is the use of modular (NbTi) superconducting coils to produce the required magnetic equilibrium. The coils could therefore be manufactured off-site, rather than onsite, as in the heliotron concept. The magnetic configuration also produces an associated “island divertor” via a series of magnetic islands generated at the plasma edge, thereby generating a means of power and particle exhaust. Alternative blanket concepts studied for the HSR devices are a helium-cooled ceramic breeder or an LiPb breeder with helium- or water-cooling. A self-cooled LiPb option was also considered. As in the FFHR design, the blanket segmentation was arranged to allow replacement of the blanket without disturbance of the superconducting coil system.

The final concept illustrated in the table, ARIES-CS (Najmabadi et al., 2008), is based on the concept of quasi-axisymmetry (QAS), see, e.g., (Yamada, 2021), an alternative form of plasma optimization to that applied in the Helias concept. The magnetic configuration, with three toroidal periods, is produced predominantly by a set of modular coils, but a small plasma current (4 MA) is also exploited and the equilibrium was designed to generate this via the pressure-driven, i.e., bootstrap, current in the plasma to avoid the need for an external source of steady-state non-inductive current drive, as is required in tokamaks. The aim of this approach was to allow the design of a more compact reactor design, on a scale comparable to typical tokamak reactor concepts, targeting a COE comparable to that derived for tokamak FPPs. Optimization of the plasma configuration aimed to obtain a smaller aspect ratio than possible with the heliotron and Helias designs while simultaneously minimizing the α -particle losses, a key physics issue for helical systems. The compact size of the device, resulting in a peak magnetic field of ~ 15 T at the coils, necessitated the use of Nb₃Sn superconductor operating at 4 K, and this implied a significantly more complex manufacturing process than for tokamak TF and CS coils. The breeding blanket geometry is also complex and in areas with insufficient space between the plasma and the coils, a tapered breeding blanket with an additional WC shielding blanket was employed. The breeding blanket used a self-cooled PbLi breeder with an additional He circuit to cool the RAFM steel structure. Due to the complex plasma equilibrium, the peak neutron wall loading is a factor of two greater than the average figure of 2.6 MWm^{-2} given in the table. This limits the blanket lifetime to ~ 3 FPY. A further challenge relates to the divertor concept and control of PFC heat loads: the divertor configuration approximates a toroidally threefold version of the tokamak double-null divertor configuration, but the design was not fully optimized to ensure PFC power handling constraints were entirely respected.

Reversed field pinch concepts

Interest in the development of reactor concepts around the reversed field pinch (RFP) has been limited by the poor plasma energy confinement associated with the dynamo action which generates the magnetic configuration. As discussed by Zuin (2021), RFP research is addressing this limitation through the use of active control of the current profile and of MHD instabilities. Nevertheless, several FPP studies using an RFP fusion core have already been developed, motivated by the possibility of operation at high values of β (several tens of percent), as already demonstrated experimentally, implying a more economic exploitation of the confining magnetic field. Early studies on this approach undertaken in the 1970s and 1980s are discussed by Conn (1981) and Krakowski et al. (1986a,b). Perhaps the most detailed approach to the development of an RFP FPP design concept was undertaken within the TITAN study. Parameters of the TITAN-I device (Najmabadi et al., 1993a,b) are listed in Table 3. A variant of this concept, TITAN-II, with essentially the same device parameters and similar electrical power output, but using somewhat different technology, was also analyzed (Wong et al., 1993).

Striking features of this design concept, scaled to produce nearly 1 GWe, include the very compact dimensions of the device, with a major radius of 3.9 m, and the high value of β_p , 23%, resulting in a very high average neutron wall load, 18 MWm^{-2} . Although this neutron wall load would now likely be considered unacceptable, the overall aim of the study was to investigate the implications of exploiting the potential for a compact high power FPP associated with the RFP configuration, in particular to analyze the technical feasibility and principal development issues for such a concept. Several key physics assumptions were incorporated in the design that are still to be resolved within the RFP research program, e.g., (Zuin, 2021), including sustainment of sufficiently high energy confinement to achieve the required fusion gain and fusion power production, the efficiency and feasibility of exploiting oscillating field current drive (OFCD) to maintain the plasma current, which is the sole source of plasma heating and is an essential element of the magnetic configuration, and the feasibility of the approach to handling power and particle exhaust using toroidal divertors (as opposed to the poloidal divertors used in tokamaks, which are toroidally symmetric). The magnet system used both helium-cooled copper conductors, in particular for the ohmic heating circuit, and NbTi superconductors. Vanadium alloy was selected for all in-vessel structures and for the vacuum vessel due to its radiation resistance and capability for high temperature operation. The former feature was critical given the high average neutron wall load. Nevertheless, it was foreseen to replace the entire torus structures annually, and this requirement was incorporated into the plant layout. Although it was noted that certain features of the vanadium alloy might mitigate corrosion by the liquid lithium, this issue would require further R&D.

Overall, the TITAN concept was a highly ambitious approach to an FPP design which, nevertheless, sought to understand the implications of fusion power production in a very compact system. Further developments of several physics and technology aspects of the concept, including the implications for the COE, were discussed by Müller (2009). Subsequently, RFP research has focused on resolving the key physics issues limiting plasma fusion performance and there has been no further conceptual developments towards an FPP with a pure fusion RFP at its core. However, a proposal for a fusion-fission hybrid reactor using an RFP as the fusion neutron source has recently been developed (Piovan et al., 2018, 2020).

Table 3 Principal parameters of the TITAN reversed field pinch power plant study.

Parameter	TITAN-I (Najmabadi et al., 1993a,b)
Toroidal field (plasma surface) (T)	0.36
Plasma current (MA)	17.8
Major, minor radius (m)	3.9, 0.6
Aspect ratio (R/a)	6.5
β_p	23%
Plasma volume (m ³)	28
Auxiliary power ^a (MW)	0
Fusion power (MW)	2301
Total thermal power ^b (MW)	2935
Net electrical power (MW)	970
Av. neutron wall load (MWm ⁻²)	18
Operation mode ^c	Steady-state
Thermal Cycle	Rankine
Thermal efficiency, η_{th}	0.44
Recirculating power fraction (1/Q _{Elec})	0.25
First wall material	V-3Ti-1Si
First wall structure	V-3Ti-1Si
First wall coolant	Liquid Li
Breeding blanket structure	V-3Ti-1Si
Breeding material	Liquid Li
Breeding blanket coolant temp. (K)	970
Breeding blanket coolant	Liquid Li
Shield blanket material	V-3Ti-1Si
Vacuum vessel structure	V-3Ti-1Si

^aPlasma is heated entirely by ohmic heating produced by plasma current.

^bSee Table 1, footnote b.

^cSteady-state power production is maintained by oscillating field current drive (OFCD).

Fusion-Fission hybrid reactors

The fusion-fission hybrid reactor concept noted in the previous section was originally developed during the initial decades of fusion research, see, e.g., (Moir, 1981). A hybrid reactor has a fusion device at its core which is surrounded by a blanket which not only breeds tritium from lithium to sustain the fusion fuel cycle, but has a sub-critical assembly of fissile material which uses the fusion neutrons to sustain the fission reactions and converts fertile material, such as ²³²Th or ²³⁸U, into fissile material, i.e., ²³³U or ²³⁹Pu. A hybrid reactor is capable of net electricity production, and a significant electrical gain factor, Q_e , from a low fusion gain core, $Q_{th} \sim 1-3$, while producing fissile material and “burning” nuclear waste. It would allow the exploitation of fusion energy with significantly lower fusion performance (and hence more modest plasma parameters) than for a pure fusion device. However, the technical complexity of the hybrid core, as well as the environmental, safety and nuclear proliferation issues associated with the hybrid concept, are more challenging than for a pure fusion device. The following paragraph touches on several references which can provide an introduction to this area of research without attempting to address the scientific, technical and environmental issues involved in the conceptual designs or their implementation.

The key concepts associated with the hybrid reactor are presented in tutorial form by Stacey (2012). In addition, a detailed review of the research program required to advance the realization of this approach can be found in Freidberg et al. (2009). The scope of contemporary research activities on this topic, which are perhaps most vigorously pursued in China and Russia, can be found in the proceedings of the International Conferences on Fusion-Fission Sub-Critical Systems for Waste Management and Safety, e.g., (Pizzuto and Orsitto, 2017, 2019). A range of toroidal and linear fusion devices have been considered as suitable neutron sources within conceptual designs for hybrid systems and more detailed presentations of specific concepts can be found in, e.g., (Wu et al., 2006; Ryutov et al., 2010; Stewart and Stacey, 2014; Kuteev et al., 2017; Stacey, 2017; Piovan et al., 2018).

Conclusions

The magnetic fusion research program is still addressing a range of significant challenges in both science and technology, and the realization of a fusion power plant remains several decades in the future. Nevertheless, the conceptual studies of FPPs undertaken in recent decades, of which only a subset has been reviewed here, have been essential in deepening the understanding of how the scientific and technological solutions resulting from the ongoing research must converge to a self-consistent system which is capable of large-scale electricity production at a cost which is likely to be economically acceptable. It must also be emphasized that the various conceptual designs reviewed here are likely to be representative of different phases in the eventual implementation of a fleet of FPPs.

As discussed by [Donné et al. \(2021\)](#), the scale and complexity of an FPP is likely to require a rather conservative development path towards commercial electricity production, and this is reflected in current concepts for a DEMO reactor—the “proof-of-principle” step for fusion electricity production and the next step beyond ITER towards construction of the first FPPs. However, if this development program is successful, it can be anticipated that the extensive natural fuel resources available for fusion energy, together with its favorable safety and environmental characteristics, will encourage the exploration of more advanced, potentially more cost-effective, concepts for fusion reactors. Even the most scientifically and technologically ambitious of the concepts reviewed in the preceding discussion can be expected to evolve under the influence of results from the current R&D program, in particular from ITER, which will provide the first opportunity for the study of burning plasmas at the reactor scale. They nevertheless underline the options available in the longer term for refining the design of FPPs towards lower COE.

The timescale for construction of the first (commercial) FPP remains uncertain and there are opportunities in the ongoing R&D programs that could accelerate the steps to demonstrating the scientific, technical and commercial viability of fusion. Examples include the development of large-scale HTS-based magnets, which might support more compact reactor designs, nuclear qualification of improved radiation-resistant structural materials that can operate at higher temperature, improving the power plant thermal efficiency, and a demonstration of liquid metal plasma facing components that can operate in the burning plasma environment, which might allow longer operational periods between in-vessel interventions for component replacement. Such opportunities should therefore be pursued in parallel with the current major thrusts of the magnetic confinement program developed around ITER and DEMO, the further exploration of the reactor potential of the stellarator configuration and the construction of a high-intensity fusion neutron source for the qualification of reactor-relevant materials.

Introduction

Net release of energy by fusion reactions requires the attainment of very high temperature as well as appropriate *confinement* of the reacting materials, at the plasma state. By confinement we refer to a mechanism allowing to maintain burning fusion conditions for a sufficiently long time, so that the energy released exceeds the energy spent to create and sustain the burning plasma configuration.

In magnetic confinement fusion (MCF), a relatively low density plasma is kept in a quasi-steady-state in which power losses from the plasma are compensated by power delivered by fusion products and, if required, by auxiliary heating systems. The relevant necessary condition is expressed by the Lawson criterion, $n\tau_E > \zeta(T)$, requiring that the product $n\tau_E$ of ion density n times energy confinement time τ_E exceeds a certain function of the temperature $\zeta(T)$. Characteristic reference values for an equimolar deuterium-tritium (DT) plasma, at temperatures of 10 – 15 keV, are $\zeta \approx 10^{14} \text{ cm}^{-3} \text{ s}$, $n = 10^{14} \text{ cm}^{-3}$ and $\tau_E \approx 1 \text{ s}$. (Here and in

most of this Chapter we will consider DT fuels; advanced fusion fuels are briefly dealt with in Section “*ICF with deuterium and advanced fuels*”).

Inertial confinement fusion, ICF, takes a radically different approach: fusion conditions are achieved in a strongly compressed and hot fusion fuel, with such a large pressure (hundreds of billion of atmospheres) that no containment is feasible, other than that due mass inertia. The fuel remains in the compressed state for the time τ a rarefaction wave (proceeding with the isothermal sound speed c_s) takes to propagate through it. For a sphere of radius R , we may consider a fuel averaged confinement time $\tau \approx R/4c_s$, with the factor 4 in the denominator accounting for the earlier rarefaction of the outer layers, which contain most of the sphere mass. For a fully ionized DT plasma, $c_s = 2.8 \times 10^7 \sqrt{T}$ cm/s, with T the temperature in keV. It follows that the confinement time of an ICF burning plasma, with $R \approx 100 \mu\text{m}$ and temperatures of tens of keV is as short as 100 ps or less. Notice that while for steady state MCF plasmas we consider an energy confinement time, here the relevant time τ is a matter confinement time.

As detailed in the following, typical values of particle density are in the range of $10^{25} - 10^{26} \text{ cm}^{-3}$ in ICF. Fusion reactions occur in a time interval comparable to (or shorter than) such a confinement time. A prospective inertial fusion energy (IFE) reactor will therefore release energy in a sequence of micro-explosions, to be contained within the reactor. If the energy release is limited to 1 GJ per target, the burnt mass in a target cannot exceed 3 mg, since the specific yield (energy released by complete burn) of DT is $Y_{\text{DT}} = 337 \text{ MJ/mg}$.

In an IFE power plant suitable *targets* containing small quantities of fusion fuels will be burned at a rate of 1–10 Hz. Energy to heat and compress the target is provided by a powerful pulsed *driver*, such as a laser. Of course, operation of the plant requires that the produced energy exceeds (by far) the energy necessary to operate the driver. In this context, target energy gain, or simply *gain* $G = E_{\text{fus}}/E_d$, ratio of fusion energy released by a single target to the energy in the driver pulse, is a particularly important figure of merit to gauge target performance.

In the following sections of the present Chapter we discuss confinement and compression requirements, ignition conditions, as well as conditions for the achievement of high gain. We show how compression requirements, ignition conditions, and ignition modality follow from the need of significant gain in a containable micro-explosion. We also briefly illustrate different schemes which have been proposed to compress and ignite ICF fuels. The reader interested in more detailed treatments is referred to the textbook by [Atzeni and Meyer-ter-Vehn \(2004\)](#) and to the review papers by [Brueckner and Jorna \(1974\)](#), [Lindl \(1995\)](#), [Lindl et al. \(2004\)](#), [Craxton et al. \(2015\)](#), and [Betti and Hurricane \(2016\)](#). A pedagogical treatment of the basic plasma physics of ICF can be found in an article by [Tikhonchuk \(2021\)](#).

Basic requirements

IFE plant energy cycle and target gain

We now consider a simplified IFE power plant energy cycle. The fuel containing target is irradiated by driver (e.g. laser) pulses of energy E_d , obtained by converting electrical energy into beam energy (photons) with efficiency η_d . The irradiated target releases fusion energy $E_{\text{fus}} = GE_d$, with a gain G . Such an energy is first converted into thermal energy in a suitable blanket, and then into electrical energy through a thermal cycle, with efficiency $\eta_{\text{th}} \approx 40\%$. A fraction f of this electrical energy is used to energize the laser, hence $\eta_d G \eta_{\text{th}} f = 1$. Requiring recycled electrical energy fraction $f \leq 25\%$, we obtain

$$G \eta_d \geq 10. \quad (1)$$

For driver efficiency of 10%, as predicted for future reactor-size lasers ([IAEA, 1995](#)), target gain $G \geq 100$ is required. Smaller gains can be allowed by potentially more efficient drivers, such as heavy ion accelerators, which could achieve $\eta_d \approx 25\%$.

The power plant delivers to the grid electrical power $W = \nu_d(1 - f)\eta_{\text{th}}GE_d$, where ν_d is the shot frequency. A set of possible values for a 900 MW power plant is $E_d = 3 \text{ MJ}$, $\eta_d = 10\%$, $\nu_d = 10 \text{ Hz}$, $G = 100$, $f = 25\%$. For simplicity, the above considerations do not include an additional power multiplication, by a factor of about 1.1, due to exothermal neutron induced reactions in the reactor blanket.

Key requirements for high gain ICF are identified by simple considerations on target gain G . The driver pulse energy is used to compress and heat the target; however (see, e.g. [Tikhonchuk, 2021](#)) only a fraction η_c , typically 5–10% in the conventional direct-drive schemes discussed in Section “*Conventional beam-driven spherical implosion*,” is actually transferred to the fuel mass m . We can then write

$$G = \frac{E_{\text{fus}}}{E_d} = \frac{m\Phi Y_{\text{DT}}}{me/\eta_c} = \eta_c \frac{\Phi}{e} Y_{\text{DT}} = 100 \left(\frac{\eta_c}{0.1} \right) \left(\frac{\Phi}{0.3} \right) \left(\frac{10^{15} \text{ erg g}^{-1}}{e} \right) \quad (2)$$

with m the fuel mass, Φ the fuel fractional burn-up, Y_{DT} the specific DT yield, and e the specific energy (energy/mass) delivered to the fuel. According to Eq. (2) gain of the order of 100 implies fractional burn of 20–30% from a fuel with mass averaged specific energy of the order of $10^{15} \text{ erg g}^{-1}$. In the next two subsections, we show that two basic ingredients of high gain ICF, namely strong compression and hot spot ignition, just follow from the requests of relatively large Φ and relatively small e .

Fractional burn, confinement and compression

A first estimate for the fractional burn Φ is given by the ratio τ/τ_b of the confinement time τ defined earlier to the characteristic nuclear burn time. For a deuterium or tritium nucleus in an equimolar DT plasma with nuclei density n , $\tau_b^{-1} = (1/2)n \langle \sigma v \rangle$, where $\langle \sigma v \rangle = \langle \sigma v \rangle(T)$ is the Maxwellian averaged reactivity of the D - T fusion reaction, with σ the reaction cross section and v the relative velocity of the reacting nuclei.

For a homogenous spherical fuel we then have

$$\Phi = \frac{nR \langle \sigma v \rangle}{8c_s} = \frac{\rho R}{H_b}, \quad (3)$$

where ρ is the mass density, ρR is the so called ICF confinement parameter, and $H_b = H_b(T) = 8m_i c_s / \langle \sigma v \rangle$ is the ICF burn parameter. Eq. (3) only applies for small values of Φ and homogeneous fuels. A more general expression, accounting for fuel consumption and inhomogeneity is

$$\Phi = \frac{\langle \rho R \rangle}{\langle \rho R \rangle + H_b}, \quad (4)$$

where $\langle \rho R \rangle = \int \rho dR$ over the whole fuel. For an ignited DT fuel, with $T = 20 - 80$ keV, the temperature dependence of H_b is weak and one can take $H_b = 7 \text{ g cm}^{-2}$ as a reference value. Fractional burn of 30% then requires $\langle \rho R \rangle = 3 \text{ g cm}^{-2}$. Achieving such a value of the confinement parameter with a mass of at most a few mg, implies strong compression. For a homogenous sphere $m = (4/3)\pi(\rho R)^3/\rho^2$. It follows that

$$\rho = \sqrt{\frac{4\pi(\rho R)^3}{3m}} = 194 \left(\frac{\rho R}{3 \text{ g cm}^{-2}} \right)^{3/2} \left(\frac{m}{3 \text{ mg}} \right)^{-1/2} \text{ g cm}^{-3}. \quad (5)$$

Average density of at least 200 g cm^{-3} , i.e. 800 times DT solid density is required. Even stronger compression is necessary for the smaller targets to be irradiated in experiments aiming at demonstrating ignition.

Hot spot ignition

A second key requirement follows from limiting the average fuel specific energy at ignition to $e_{\max} \sim 10^{15} \text{ erg g}^{-1}$ (see Eq. 2). According to the ideal gas equation of state, $e = C_v T$ with the DT specific heat $C_v = 1.15 \times 10^{15} \text{ erg g}^{-1} \text{ keV}$, this corresponds to a DT temperature of 870 eV. Such a temperature is well below the ideal ignition temperature of 4.3 keV at which the power associated to the 3.5 MeV alpha-particles released by the DT fusion reaction equals the bremsstrahlung power loss. Heating the whole fuel to temperature of 4 – 5 keV or larger would result in unacceptably low gain. The solution is *spark ignition* or *hot spot ignition*. Only a small part of the fuel is heated to the high temperature necessary to trigger effective fusion burn. Such a hot spot first self-heats and ignites due to the energy delivered by the fusion alpha-particles, and then drives a burn wave which ignites the remaining cold fuel. Of course, as discussed in the next section, the hot spot parameters must satisfy specific conditions, concerning confinement parameter and temperature, in order to self-heat and ignite. In addition, in order to make use of the driver energy in the most efficient way, the main fuel should be compressed by keeping its temperature as low as possible. Ideally, one would like to produce a cold plasma. In practice, the main fuel will be heated to some (relatively low) temperature T_c and will have pressure $p_c = p_c(\rho_c, T)$. Compression is characterized by the ratio

$$\alpha = p_c(\rho_c, T)/p_d(\rho_c) \geq 1, \quad (6)$$

i.e. the ratio of the actual fuel pressure to the pressure $p_d = A_d \rho^{5/3}$ of a cold gas with degenerate electrons. Here $A_d = 2.15 \times 10^{12} \text{ (erg g}^{-1}) \text{ (g cm}^{-3})^{-2/3}$. Since this ratio is proportional to entropy and is therefore constant during isentropic compression, it is usually called *isentropic parameter* or *adiabat*. The achievement of strong compression with low entropy generation, i.e. with small values of α is discussed, e.g., by Tikhonchuk (2021).

Hot spot ignition

Hot spot ignition conditions depend on the specific mechanism leading to the generation of the compressed fuel assembly. However, relevant information is obtained by considering the simple case of a central hot spot in a spherical fuel, initially at rest. It is assumed that such a configuration is generated as the target implosion stagnates, i.e. at the time of maximum compression of the fuel. In the spirit of this over-simplified model we assume that the hot spot is a homogeneous sphere of DT of radius R_h , with mass density ρ_h and temperature T_h . The surrounding fuel, with mass $m_c \gg m_h$, is also homogeneous, with density ρ_c and temperature $T_c \ll T_h$. Due to its high temperature the hot spot specific energy is that of an ideal gas, $e_h = C_v T_h$, while the colder fuel energy can be parametrized as $e_c = (3/2)\alpha A_d \rho_c^{2/3}$. It follows that the average specific energy of the igniting fuel assembly can be written as

$$e \approx (m_h/m_c) C_v T_h + (3/2)\alpha A_d \rho_c^{2/3}. \quad (7)$$

Fig. 1 Fuel configuration at ignition: (A) isobaric; (B) isochoric, illustrated by radial profiles of density (black), temperature (red) and pressure (blue). The significance of these two approaches is discussed in Section “Hot spot ignition.”

Two limiting cases are of particular interest (see Fig. 1). In the first one the compressed assembly is isobaric, i.e. the pressure is uniform over the whole fuel. In this case the hot spot is surrounded by much denser fuel. In the other case (isochoric assembly) the density is uniform and then the hot spot pressure substantially exceeds the cold fuel pressure. Isobaric conditions are a good approximation to the actual state of the compressed fuel in conventional ICF implosions, sketched in outline in the following Section “Conventional beam-driven spherical implosion.” Isochoric conditions, instead, are relevant to fast ignition schemes (Section “Fast ignition”), in which the fuel is first compressed to high density and then the hot spot is generated by an ultra-intense external particle beam pulse of duration shorter than the energy confinement time of the hot spot itself.

Hot spot power balance and hot spot self-heating conditions

The time evolution of the hot spot internal energy is ruled by a competition between heating by fusion alpha-particles (delivering a power density $W_{\alpha-in}$ inside the hot spot), and cooling by bremsstrahlung radiation (W_b) and thermal conduction (W_{th}). In the isochoric case, an additional loss is due to the mechanical work (with power density W_m) performed by the hot spot that expands, since its pressure exceeds that of the surrounding fuel. Neutron interaction is energetically negligible for typical hot spot parameters. The 3.5 MeV alpha-particles, which carry 1/5 of the DT fusion energy, have a finite range l_α and then deposit a fraction f_{in} of their energy in the hot spot itself. A first, rough evaluation of the ignition conditions can then be obtained as follows. Alpha-particle range, determined by Coulomb interactions with plasma electrons and ions, can be written as $l_\alpha \approx 0.025 T_h^{1.25} \rho_h^{-1} \text{ cm}$ (Fraleigh et al., 1974), for temperatures below 30 keV and densities in the range $10 - 100 \text{ g cm}^{-3}$. The fraction f_{in} then turns out to be a function of the ratio $\xi = R_h/l_\alpha$; in particular, for $\xi > 1/2$, $f_{in} \approx 1 - 1/4\xi$ (Gus'kov et al., 1974). It follows that, at temperatures 5 – 7 keV, when the alpha-particle power starts exceeding bremsstrahlung losses, a necessary condition for hot spot self-heating is a substantial containment of alpha-particles, which requires $\xi \approx 1$. The hot spot confinement parameter (product of density and radius) should satisfy $\rho_h R_h \approx \rho_h l_\alpha$. At temperature $T_h = 7 \text{ keV}$, $\rho_h R_h \approx 0.3 \text{ g/cm}^2$.

For a more accurate calculation, let us now consider the rate of change of the hot spot energy density ε_h

$$d\varepsilon_h/dt = W_{\alpha-in} - W_b - W_{th} - W_m, \quad (8)$$

where the individual power terms can be written as

$$W_{\alpha-in} = f_{in} A_\alpha \rho_h^2 < \sigma v >, \quad (9)$$

$$W_b = A_b \rho_h^2 T_h^{1/2}, \quad (10)$$

$$W_{th} = A_{th} T_h^{7/2} / R_h^2 = A_{th} \rho_h^2 T_h^{7/2} / (\rho_h R_h)^2, \quad (11)$$

$$W_m = (p_h/V_h)(dV_h/dt) \quad (12)$$

We have used standard expressions for fusion power density and bremsstrahlung power density. The conduction term is obtained using dimensional arguments and the usual Spitzer (Spitzer and Härm, 1953) formula for electron thermal conductivity, $\chi \propto T^{5/2}/\ln \Lambda$, where $\ln \Lambda$ is the Coulomb logarithm, weakly depending on both temperature and density. The quantities A_α and A_b are constants, with values $A_\alpha = 8 \times 10^{40} \text{ erg g}^{-2}$ and $A_b = 3.05 \times 10^{23} \text{ erg cm}^3 \text{ g}^{-2} \text{ s}^{-1} \text{ keV}^{-1/2}$, $A_{th} \approx 2.9 \times 10^{20} / \ln \Lambda \text{ erg s}^{-1} \text{ cm}^{-1} \text{ keV}^{-7/2}$, with $\ln \Lambda \approx 5$ in cases of interest here. Approximate expressions for $f_{in} = f_{in}(\xi)$ are given by Gus'kov et al. (1974). Mechanical power is zero in the isobaric case, since the hot spot initially does not expand. In the isochoric case (with $p_h \gg p_c$), instead, the hot spot expands suddenly, and an outward directed shock wave is driven. The expansion velocity can be

Fig. 2 Hot spot self-heating boundaries (thick curves) and ignition boundaries (dashed curves) in the $\rho_h R_h - T_h$ plane, for (A) isobaric initial conditions and (B) isochoric initial conditions. Hot spots with initial parameters in the orange areas self-heat; hot spots with initial parameters in the yellow areas eventually self-heat and ignite after an initial cooling stage, as shown by the dotted curves originating from point C in frame (A) and from point D in frame (B). Points A and B indicate reference cases leading to ignition with hot spot initial energy close to a minimum.

approximated as that of the material behind a strong shock wave propagating in a homogeneous medium (Zel'dovich and Raizer, 1967), $u_h = dR_h/dt \approx (3p_h/4\rho_c)^{1/2} = (3p_h/4\rho_h)^{1/2} = (C_v T_h/2)^{1/2}$. We then write

$$W_m = A_m \rho_h T_h^{3/2} / R_h = A_m \rho_h^2 T_h^{3/2} / (\rho_h R_h), \quad (13)$$

with $A_m = 5 \times 10^{22} \text{ cm}^3 \text{ s}^{-3} \text{ keV}^{-3/2}$. From Eqs. (9)–(11) and (13) it is apparent that a self-heating condition $dE_h/dt > 0$ can be written in the form

$$\rho_h R_h > g(T_h), \quad (14)$$

when the weak dependence of the Coulomb logarithm on temperature and density is neglected. The self-heating boundaries computed for both isochoric and isobaric ignition conditions are shown in Fig. 2, and found to agree with the results of detailed hydrodynamic simulations. Hot spots with initial parameters in the orange areas self-heat.

Hot spot ignition conditions

It is important to notice, however, that also initial conditions falling outside the self-heating region can eventually lead to fuel ignition and propagating burn. Indeed, for initial conditions in the yellow area in the figure, the hot spot at first cools, but the energy lost by thermal conduction and the energy deposited by the alpha-particles just outside the hot spot heats a layer of initially colder fuel surrounding the hot spot (notice that the cold fuel is a more efficient stopper than the hot spot). This fuel is ablated and enters the hot spot, increasing its density and then its ability to contain the alpha-particles. This may lead, as in the cases represented by the dotted curves originating from point C in Fig. 2A) and from point D in Fig. 2B), to eventual self-heating and ignition (Atzeni and Caruso, 1984). We can then define an ignition boundary of the same form as (14) as the separatrix between initial conditions finally leading to fuel burn and those leading to cooling. Ignition boundaries, determined by detailed numerical simulations, are represented by the thick dashed curves in Fig. 2. The curve for isobaric conditions, which also depends on the density ratio $r_\rho = \rho_c/\rho_h$, is plotted for $r_\rho = 16$. The figure also shows two points, A and B, corresponding to non-marginal ignition at nearly minimum energy for isobaric and isochoric conditions, respectively. In case A, $\rho_h R_h = 0.25 \text{ g cm}^{-2}$, $T_h = 7 \text{ keV}$; in case B, $\rho_h R_h = 0.50 \text{ g cm}^{-2}$, $T_h = 12 \text{ keV}$. The corresponding hot spot energy is

$$E_h = (4\pi/3) R_h^3 \rho_h C_v T_h = E_0 \left(\frac{\rho_h}{100 \text{ g cm}^{-3}} \right)^{-2}, \quad (15)$$

with $E_0 = 5.2 \text{ kJ}$ for case A (isobaric), and $E_0 = 72 \text{ kJ}$ for case B (isochoric).

Designed ignition experiments and prospective reactor targets exploiting isobaric ignition aim at generating hot spots with density of $50 - 100 \text{ g cm}^{-3}$, radius of $30 - 50 \mu\text{m}$, surrounded by a denser fuel with density up to 1000 g cm^{-3} . Fast ignition schemes consider nearly uniform density of $300 - 500 \text{ g cm}^{-3}$, and then hot spot radii of $10 - 20 \mu\text{m}$.

The ICF ignition conditions, in the form $\rho_h R_h > g(T_h)$, are analogous to the Lawson criterion $n\tau_E > \zeta(T)$ for magnetic confinement fusion. Interestingly, also for ICF, we can identify a metric for progress towards ignition analogous to the MCF triple product $n\tau_E T$. In Fig. 3, we plot the quantity $\rho_h R_h T_h r_\rho^{1/2}$ needed for ignition according to full simulations, for the isochoric case and for an

Fig. 3 Ignition condition in a form similar to the triple product considered in magnetic fusion. The thick dashed line represents the ignition condition (16); the green and yellow areas, denote hot spot ignition regions for isochoric and isobaric initial condition, respectively.

isobaric case with $r_\rho = 16$. We see that the two curves are close to each other for temperature $T_h > 6$ keV. A general, approximate ignition condition can then be written as

$$\rho_h R_h T_h \geq 5/\sqrt{r_\rho} \text{ g cm}^{-2} \text{ keV}; \quad T_h > 6 \text{ keV.} \quad (16)$$

or, using $p_h = (2/3)\rho_h e_h$,

$$p_h \geq 400 \left(\frac{10}{r_\rho} \right)^{1/2} \frac{30 \text{ } \mu\text{m}}{R_h} \text{ Gbar,} \quad (17)$$

where the hot spot radius is normalized to a typical value of $30 \mu\text{m}$. Eq. (17) shows that the hot spot pressure at ignition in typical conventional ICF cases is somewhat larger than the pressure at the Sun center (250 Gbar).

Following ignition, a burn wave propagates outward. In its first stage, its dynamics are characterized by the self-regulation of the size of the burning region to range of the alpha-particles (which increases with temperature, roughly as $T^{5/4}$). Other regimes of burn propagation can occur at very high temperatures. In any case, the fractional burn is essentially a function of the confinement parameter $\langle \rho R \rangle$ only.

Low temperature volume ignition

The previous discussion on ignition conditions assumes that emitted bremsstrahlung radiation escapes from the hot spot. This is a good approximation for the hot spots considered so far, since the characteristic Rosseland mean free path of thermal photons (Zel'dovich and Raizer, 1967) in DT is $l_R = 400 T^{7/2} \rho^{-2} \text{ cm}$, with the temperature in keV and the density in g cm^{-3} . However, a uniformly heated mass of dense hot fuel, with radius comparable to or larger than l_R , reabsorbs most of the emitted energy. In this case volumetric emission is replaced by surface emission. The fuel can now self-heat also at low temperature, if the confinement time is sufficiently long (Caruso, 1974). At large $\rho R \geq 5 \text{ g cm}^{-2}$ the fuel ignites at temperature of the order of 1.5 keV or lower. Note however that, even neglecting the contribution due to compression, the fuel specific energy is still too large to allow for large fusion gain. In addition, the large value of ρR required implies either large mass (and then large drive energy) or extremely high density, and self-heating is relatively slow, so that fractional burn up is smaller than the value computed using Eq. (4).

ICF with deuterium and advanced fuels

The preceding discussion only concerns DT fuels and the D-T reaction

Other fusion reactions and therefore other fuels are of potential interest. We refer in particular to the reactions

Table 1 Key properties of thermonuclear fusion fuels.

The DT mixture is the main candidate fuel for IFE because the reactivity of the D-T reaction is by far larger than that of any other reaction at temperature $T < 100$ keV. Pure deuterium is an attractive fuel, due to its practically unlimited availability. D-D reactions also produce T and ^3He , which can react with other D nuclei, through D-T and D- ^3He reactions. This so-called *catalytic burn* increases significantly deuterium reactivity, but to levels still much below that of DT. The reactivity of D- ^3He is higher than that of deuterium at $T > 25$ keV, and the reaction D- ^3He does not release neutrons. However in a D ^3He fuel D-D reactions occur. Additionally, ^3He is only found in extremely small quantities on Earth. A hydrogen-boron mixture would release a negligible amount of neutrons, but p- ^{11}B reactivity becomes comparable to that of the other, D-based, fuels only at temperatures of the order of 100 keV.

Key parameters to evaluate the potential of fusion fuels, namely, ideal ignition temperature assuming equal electron and ion temperatures, T_{id} , minimum value, H_b , of the burn parameter, and specific yield, Y , are listed in Table 1. It is seen that p- ^{11}B cannot be ignited, while D-based fuels have ignition temperatures significantly higher than that of DT. The burn parameter of DT is much smaller (and then burn-up of a fuel with given ρR is much higher) than that of all other fuels. Hot spot ignition boundaries for DT and DD (including partial catalytic burn of T and ^3He) are shown in Fig. 4. In conclusion, high gain burn of pure D or advanced fuels does not appear feasible, at least using the ICF schemes discussed in this Chapter. Large and dense assemblies of deuterium or D- ^3He mixtures could instead be ignited by the burn wave generated by thermonuclear burn of a DT seed (Tabak, 1996; Atzeni and Ciampi, 1997).

Compression and ignition options: Conventional and advanced schemes

Conventional beam-driven spherical implosion

Qualitative description

According to the previous section, an IFE target should contain a few mg of DT fuel, which must be compressed to an average density of at least 1000 times solid density and low average entropy. In addition a hot spot with a pressure of 300–500 Gbar and sufficiently large radius has to be generated.

The standard scheme to generate such a compressed fuel configuration is beam-driven implosion (Nuckolls et al., 1972) of a millimeter sized hollow shell, schematically illustrated in Fig. 5. Here we consider laser-driven implosion, but the laser beams can be replaced by thermal X-rays or, possibly, by heavy ion beams. The target is in the form of a hollow shell (Kidder, 1976), rather

Fig. 5 Laser-driven implosion: (A) irradiation; (B) ablatively driven implosion; (C) compression and hot spot formation; (D) ignition and burn. Adapted from the original in Atzeni and Meyer-ter-Vehn (2004) *The Physics of Inertial Fusion*. Oxford University Press, reproduced with permission of Oxford University Press through PLSclear.

than a full sphere, to increase its outer surface, thus allowing for less intense and longer pulses (see below). The initial fuel aspect ratio (ratio $R_0/\Delta R$ of the fuel outer radius to the thickness of the fuel layer) is of the order of 10; larger values make the target too sensitive to instabilities. The fuel is solid DT (at temperatures of 17 – 19 K) in order to minimize the required compression. It is surrounded by a layer of material (plastic, beryllium, carbon) which absorbs laser light and provides structural robustness. DT vapor, with pressure equal to the vapor pressure of the solid DT, fills the shell interior.

We now briefly describe the implosion process, obtain the values of a few characteristic parameters, and outline a few key issues for the feasibility of ICF. Upon uniform laser irradiation the target outer layers are heated, removed (ablated) and expand at high velocity. As irradiation proceeds the hot ablated material becomes transparent to laser radiation and new material is ablated for the whole duration of the pulse. As a reaction to the outward motion of the ablated material, a shock wave is sent through the solid shell. As this shock wave reaches the shell inner surface, the whole shell is set in motion and accelerates inward. The mechanism is similar to a spherical rocket, where the exhausts are the ablated materials and the payload the DT fuel and the non ablated part of the other material. In this way, a fraction $\eta_c = \eta_a \eta_h$ of the laser beam energy is transformed into kinetic energy of the imploding fuel. Here η_a is the absorption efficiency of laser light and η_h is the hydrodynamic efficiency of rocket acceleration, i.e. the ratio of the kinetic energy of the imploding fuel to the absorbed laser energy. As the imploding fuel reaches the center, it stagnates, and its kinetic energy is converted into internal energy. The fuel is then heated and compressed and the central hot spot is created, in a roughly isobaric fuel assembly. The hot spot pressure at ignition is therefore the stagnation pressure, which is a strong function of the implosion velocity. According to an analytic model (Kemp et al., 2001), confirmed by simulations,

$$p_h \propto \alpha_{if}^{-0.9} u_{imp}^3 p_a^{0.4}, \quad (23)$$

where α_{if} is the in-flight adiabat parameter of the shell, i.e. the adiabat at the end of inward acceleration. (Adiabat at stagnation will be somewhat higher, due to the generation of entropy during shell deceleration, Hermann et al., 2001.) An implosion velocity of 300–450 km s^{−1} turns out to be necessary to achieve ignition, depending on adiabat and ablation pressure.

Parameter estimate

While complex multi-physics simulations are required for a complete description of the implosion (and still, they are not fully predictive) a few main parameters can be obtained by simple considerations. A prospective reactor-size target with fuel outer radius $R = 2 - 2.5$ mm, and fuel aspect ratio 10 contains 2.5–4 mg of DT. According to Eq. (23) the target must be imploded at a velocity $u_{imp} = 300 - 450$ km s^{−1} to achieve the pressure of 400 Gbar required for ignition. The corresponding fuel specific energy is $e = v^2/2 = (5 - 10) \times 10^{14}$ erg g^{−1}, as anticipated in Eq. (2). Laser beam parameters can be estimated as follows. The pulse energy is $E_{laser} = (1/2)mv^2/\eta_c$ or

$$E_{laser} = 1.84 \frac{m}{3 \text{ mg}} \left(\frac{u_{imp}}{350 \text{ km s}^{-1}} \right)^{20.1} \frac{1}{\eta_c} \text{ MJ}. \quad (24)$$

Assuming, for simplicity, implosion at constant acceleration from the initial radius to half the initial radius, we find a beam pulse duration $\Delta t = 5 - 8$ ns. Order of magnitude values for pulse energy, time averaged laser power and intensity are then $E_L = 1 - 5$ MJ, $W_L = E_L/\Delta t = 300 - 500$ TW and $I_L = W_L/4\pi R^2 = 3 - 5 \times 10^{14}$ W cm^{−2}.

Next, we consider the ablation pressure required to accelerate the fuel at the required implosion velocity. We assume that a uniform and constant pressure p_a is applied to the outer surface of the fuel up to the time the radius is halved. We assume that internal energy is negligible with respect to kinetic energy during the implosion acceleration stage. For the kinetic energy

theorem, $p_a \Delta V = (7/8)p_a V_0 = (1/2)mv^2$, with $V_0 = (4/3\pi R_0^3)$. Writing the fuel mass as $m \simeq 4\pi R_0^2 \Delta R \rho_{DT}$, where $\rho_{DT} = 0.25 \text{ g cm}^{-3}$ is the solid fuel density, we have

$$p_a = 53 \left(\frac{u_{\text{imp}}}{350 \text{ km s}^{-1}} \right)^2 \frac{\Delta R/R_0}{0.1} \text{ Mbar.} \quad (25)$$

The above value of the ablation pressure is underestimated because the initial shell mass is greater than the final one. In addition, this is a time-averaged value. In fact, actual laser pulses must be time-shaped. Their power has to increase gradually, according to precise prescriptions, in order to avoid the generation of too strong shocks, which would cause substantial fuel preheat, thus increasing the isentrope α and hindering substantial compression; see, e.g., [Tikhonchuk \(2021\)](#). It turns out that peak value of the required ablation pressure p_a is about twice that computed according to Eq. (25).

The generation of ablation pressure of the order of 100 Mbar upon laser irradiation of a solid material at intensity $I_{\text{laser}} \leq 10^{15} \text{ W cm}^{-2}$ is discussed, e.g., by [Tikhonchuk \(2021\)](#).

Four key issues

The benefits of spherical implosion of a hollow shell are clearly evidenced by comparing the ablation pressure driving the implosion, which peaks at 100–150 Mbar, and the pressure achieved at the end of the implosion, 300–500 Gbar. Spherical implosion, with properly timed pulses, can multiply the applied pressure by a factor of several thousand! However, four critical issues have to be addressed in order to achieve ignition and high gain ([Bodner, 1981](#); [Rosen, 1999](#)).

- i) Laser light must effectively (i.e. with adequate coupling efficiency η_c) drive target implosion, which firstly requires good light absorption and then generation of ablation pressure of about 100 Mbar. It is now established that this can be achieved using pulses of vuv laser light (with wavelength λ in the range 250–350 nm), at intensities $I_{\text{laser}} \simeq 10^{15} \text{ W cm}^{-2}$.
- ii) The coupled energy must be mainly used to compress the fuel, with small entropy generation, i.e. at small value of α (but at the center of the fuel, where the hot spot has to be created). This requires careful timing of the laser pulse, to avoid generation of too strong shocks. Any other form of fuel preheating, i.e. heating during the stage of inward acceleration, should be avoided. This concerns, in particular, preheating by non-thermal electrons generated by plasma instabilities, and preheating by hard X-rays.
- iii) Departures of implosion from spherical symmetry have to be limited, to allow for the generation of a small hot spot, with a radius of the order of 1/40–1/20 of the initial shell radius. This requires extremely uniform irradiation. Long-scale relative irradiation non-uniformities should indeed be limited to about 1%.
- iv) Beam-driven implosions are subjected to hydrodynamic instabilities, in particular the Rayleigh-Taylor instability ([Taylor, 1950](#)). RTI amplifies small initial target perturbations, and may cause shell breaking, mixing of different materials, or mixing of hot and cold fuel. The deleterious effects of RTI can be reduced by (a) reducing possible instability seeds, such as target defects and short-scale laser irradiation non-uniformities (b) reducing RTI growth by suitable choices of laser pulse shaping and target materials; (c) by reducing the target in-flight-aspect-ratio (IFAR, ratio of radius to thickness during the implosion), in such a way as to keep the target thickness larger than the amplitude of the perturbations. It should be observed however, that IFAR grows with implosion velocity and decreases with α . Controlling RTI therefore conflicts with the requirements of high implosion velocity and low entropy compression required for ignition and high gain.

The above critical aspects are discussed in some detail by [Tikhonchuk \(2021\)](#). For in-depth discussions the interested reader can refer to [Atzeni and Meyer-ter-Vehn \(2004\)](#).

Direct- and indirect-drive

In the previous section we have illustrated a directly laser-driven implosion: laser beams impinge on the target, generate a high plasma pressure, and drive the implosion. An indirect-drive scheme ([Lindl, 1995](#)) is also studied (actually this is the approach favored, at least so far, by the largest laser installations). In indirect drive the fusion capsule is placed at the center of a cavity (or *hohlraum*) of a heavy material, see [Fig. 6](#). The laser beams penetrate inside the cavity through entrance holes and irradiate the inner side of the cavity, producing a layer of plasma that emits X-rays. Such X-rays are confined (actually, absorbed and re-emitted) in the cavity, which acts as a black-body. The resulting quasi-thermal radiation bath irradiates the capsule, driving its implosion.

Indirect-drive is less sensitive than direct-drive to laser nonuniformities. X-ray driven acceleration is more robust to instabilities than laser-driven acceleration ([Lindl, 1995](#)). However, the intermediate steps of X-ray generation and X-ray transfer to the capsule reduce significantly (by a factor of three or larger) the overall laser-to-fuel coupling efficiency η_c . All main aspects of indirect-drive are discussed in two extensive review papers by [Lindl \(1995\)](#) and [Lindl et al. \(2004\)](#).

Conventional ignition vs advanced ignition schemes

In the conventional implosion scheme the laser pulse provides both fuel compression and generation of the ignition hot spot at the center of a quasi isobaric assembly. Other, *advanced ignition schemes* have been proposed, in which the two stages of compression and ignition are completely or partially separated. In these cases the igniting compressed configuration is isochoric, or, anyhow, non-isobaric. Here we just outline the basic principles of advanced ignition schemes. More details can be found in [Tabak et al. \(2014\)](#) and in the references quoted therein.

Fig. 6 Inertial fusion main schemes: (A) direct-drive; (B) indirect-drive.

Eq. (17) shows that the hot spot ignition condition is essentially a condition on the pressure of the hot spot. In the conventional scheme, hot spot pressure is the pressure at implosion stagnation, which is a strong function of the implosion velocity (see Eq. 23). However, the larger the implosion velocity the more difficult is control of RTI. The confinement parameter $\langle \rho R \rangle$, instead, depends essentially on laser energy and in-flight adiabat, and very weakly on implosion velocity, $\langle \rho R \rangle \propto E_{\text{laser}}^{1/3} u_{\text{imp}}^{0.06} \alpha_{\text{if}}^{-0.55}$ (Zhou and Betti, 2006). Reducing the implosion velocity has therefore the potential advantage of reducing risks associated with the instabilities, without compromising fuel confinement. In addition, provided ignition is achieved efficiently by other means, reducing the implosion velocity could allow for significantly larger gain, since it would reduce the fuel specific energy $e = v^2/2$ (see Eq. 2). The price to be paid is that now the ignition hot spot has to be created by an additional laser pulse. We now consider separately the advanced schemes of fast ignition and shock ignition.

Fast ignition

In fast ignition (Tabak et al., 1994), the hot spot is created in a nearly homogeneous compressed fuel by an ultrapowerful particle beam. Such a beam has to produce a hot spot in an isochoric assembly, with parameters as for point B in Fig. 2, namely $\rho R_h = 0.5 \text{ g/cm}^2$ and $T_h = 12 \text{ keV}$, in a time shorter than the hot spot confinement time R_h/c_s . According to Eq. (15) the energy required scales as $E_h \propto \rho^{-2}$; pulse duration and beam radius should scale as $1/\rho$. Detailed simulations substantially confirm the above scalings, but indicate that Eq. (15) underestimates the required beam energy. The minimum beam energy, beam power, and beam intensity for fast ignition are indeed given by (Atzeni, 1999).

$$E_{\text{ig}} = 18 \hat{\rho}^{-1.85} \text{ kJ}, \quad (26)$$

$$W_{\text{ig}} = 0.9 \times 10^{15} \hat{\rho}^{-1} \text{ W}, \quad (27)$$

$$I_{\text{ig}} = 7.2 \times 10^{19} \hat{\rho}^{0.95} \text{ W cm}^{-2}, \quad (28)$$

where $\hat{\rho} = \rho / (300 \text{ g cm}^{-3})$. For a DT fuel precompressed at density $\rho = 300 \text{ g cm}^{-3}$ the igniting particle beam must deliver the above 18 kJ, in 20 ps, onto a spot of radius of $20 \mu\text{m}$. The ignition energy decreases strongly with increasing density; however, this implies reducing the beam focus and increasing beam intensity. We then take $\rho = 300 \text{ g cm}^{-3}$ as a reference density, since it is unlikely that laser beams delivering pulses of tens of kJ can be focused onto a spot with radius smaller than $15 - 20 \mu\text{m}$. An additional requirement concerns the range of the igniting particles, which should be comparable to or smaller than the desired hot spot size. The above beam parameters indeed apply to particles with mass penetration depth ρl in the range $0.15 - 1.2 \text{ g cm}^{-2}$, such as fast electrons with energy of 1–2 MeV or protons with energy of up to about 10 MeV. Notice that the above Eqs. (26)–(28) refer to deposited energy. The corresponding laser parameters should be a factor $1/\eta_{\text{ig}}$ larger, where η_{ig} is the efficiency of generation of the fast particles.

Intense electron and proton beams can be produced by ultraintense chirped-pulse-amplified (CPA) lasers (Strickland and Mourou, 1985). Electron fast ignition schemes foresee direct irradiation of the precompressed target with an ultraintense laser; see Fig. 7A. Laser interaction around critical density generates relativistic electrons, which should then reach the dense fuel and generate the hot spot. Notice that the intermediate step of propagation from the low density plasma corona to the compressed fuel involves transport of a giga-ampere current. Success of the scheme requires that hot electrons are produced with good efficiency (e.g. 20–30%), in a tightly focused, nearly parallel beam, can reach the dense fuel, and have appropriate range. Laser accelerated beams of multi-MeV protons or light ions have also been proposed as fast ignitor drivers (Roth et al., 2001). Protons can be produced by laser irradiation through many different schemes. The most studied is the TNSA mechanism (target normal sheet acceleration, from the rear side of a laser accelerated foil) (Snavely et al., 2000). A possible target configuration is shown in Fig. 7B. Being

Fig. 7 Fast ignition of precompressed fuel: (A) electron fast ignition; (B) ion fast ignition.

much more massive than electrons, protons are easier to transport and focus than electrons. Feasibility of the scheme mainly concerns the efficient generation of the ultraintense proton beam.

Shock ignition

In shock ignition (Betti et al., 2007), a first laser pulse drives implosion at a velocity somewhat lower than in conventional direct-drive. At a time close to implosion stagnation the target is irradiated (still over the full solid angle, or at least a large portion of it) by a short, intense laser pulse. This pulse, of duration of a few hundred ps and intensity of about $10^{16} \text{ W cm}^{-2}$, generates an imploding shock wave of pressure of a few hundred Mbar. The shock wave strengthens as it implodes, due to spherical convergence. When this shock-wave collides with the shock wave bouncing from the center of the previously compressed fuel the pressure is further amplified and the implosion hot spot is generated. Unlike fast-ignition, shock ignition relies on well understood hydrodynamics, and laser parameters for a demonstration are in principle compatible with present technology. Physics issues, instead, concern the interaction of the intense laser pulse with the plasma. In particular, it has to be proved that pressures of 300–500 Mbar can be generated efficiently and without producing deleterious hot electrons.

Concluding remarks

In the previous sections we have discussed the basic requirements for the achievement of net energy production by inertial confinement fusion. We have also outlined the principles of the schemes proposed to first demonstrate the feasibility of ICF, and then proceed to energy production. An important question for the current phase of research concerns laser parameters required for ignition demonstration using conventional implosion schemes. According to Eq. (15), the hot spot energy at ignition scales as $E \propto p_h^{-2}$. In turn pressure p_h scales with implosion parameters following Eq. (23). If we assume that the total fuel energy at stagnation is proportional to the hot spot energy, and that laser energy is coupled to the fuel with efficiency η_c , we obtain (Kemp et al., 2001)

$$E_{\text{laser}}^{\text{ignition}} \propto \eta_c^{-1} \alpha_{\text{if}}^{1.8} u_{\text{imp}}^{-6} p_a^{-0.8}, \quad (29)$$

This scaling is in very good agreement to the fit of a large set of detailed numerical simulations (Herrmann et al., 2001):

$$E_{\text{laser}}^{\text{ignition}} = 200 \frac{0.1}{\eta_c} \alpha_{\text{if}}^{1.88 \pm 0.05} \left(\frac{u_{\text{imp}}}{350 \text{ km s}^{-1}} \right)^{-5.89 \pm 0.12} \left(\frac{p_a}{100 \text{ Mbar}} \right)^{-0.77 \pm 0.03} \text{ kJ}. \quad (30)$$

These equations evidence the critical role of both implosion velocity and adiabat. In turn, reducing the adiabat and increasing the implosion velocity increases the risks associated with RTI growth. Furthermore, Eq. (30) assumes perfect spherical symmetry and absence of material mixing induced by RTI. In general, indirect drive allows for lower adiabat, but implies much smaller η_c . Increasing the latter in indirect-drive conflicts with symmetry requirements. Eventually, only experiments (with ingenious technical solutions) will answer the questions concerning pulse energy required for ignition and selection of the target and drive concept.

Shock ignition, which can be seen as a slightly modified conventional scheme could in principle lead to ignition at somewhat lower energy than conventional direct-drive, but the physics of strong shock generation still deserves investigation. Fast ignition potentially allows for ignition (and high gain) at much lower energy, but anyhow requires ultraintense laser pulses delivering at least 50 – 100 kJ in a few ps for hot spot generation.

Introduction

Laser-driven inertial confinement fusion is a multi-physics project involving phenomena on different spatial and temporal scales, ranging from macroscopic scales of several millimeters and nanoseconds, corresponding to the fusion target size and the whole time of the process, to the picosecond time scales, corresponding to the energy transport by charged particles and down to femtosecond times and sub-micron scales, where electromagnetic processes dominate. A good comprehension of each of these processes and their interactions is indispensable for controlling the fusion reactions and producing commercially usable energy.

A detailed presentation of all related physics goes far beyond this short review, which aims to recall the basic notions of the physics at each temporal and spatial scale, and to guide the reader to up to date developments and results with a critical analysis of unresolved issues and problems. The article is divided into two sections, addressing the macroscopic and microscopic physics, respectively.

The framework of macroscopic physics is classical hydrodynamics. Under the enormous pressure produced by tightly focused high power laser beams, the target made of a solid material behaves as a compressible fluid. It can be compressed and heated to the conditions where fusion reactions can be excited and release more energy than invested by the laser. The first half of the first section considers the ideal case of spherical symmetry. It addresses issues such as: how the laser radiation can be used for creating unique (in laboratory) pressures exceeding 100 Mbar, how this pressure should be shaped in time in order to accelerate the target to velocities exceeding 300 km s^{-1} needed for efficient fuel compression, how to implode the fuel and to achieve conditions for ignition of fusion reactions.

The real world is, however, three-dimensional, and all deviations of the target from spherical symmetry need to be well-understood and properly controlled. The analysis of three-dimensional effects in inertial fusion is presented in the second half of the first section. Small initial deviations from spherical symmetry due to the target imperfections and laser intensity modulations are unstable and grow in time during the target implosion. The two major instabilities involved in the implosion process—Rayleigh-Taylor and Richtmyer-Meshkov—are, however, strongly modified by the ablation process, and this effect provides the possibility for their control and mitigation.

The second section is dedicated to the description of microscopic processes of laser propagation, absorption and scattering and of the energy transport beyond the range accessible to the laser. One of the major particularities of laser fusion is spatial separation of the zone where laser energy can be absorbed in a relatively low density and high temperature plasma and of the high density zone where fusion reactions take place. The energy is transported between these two zones by charged particles, electrons and, in some particular cases, by ions. This is a kinetic process which cannot be reduced to a classical diffusion. The methods of description of energy transport in inertial fusion plasmas are discussed in the second half of the second section. This is one of the outstanding problems of inertial fusion theory for which an adequate solution is yet to be found.

Efficient laser energy absorption is the key to achieving energy production from fusion reactions. The classical collisional absorption of electromagnetic waves in a plasma strongly decreases as the temperature increases. Laser propagation in a plasma and the methods of improving the collisional absorption are described in the first half of the second section. These include an appropriate choice of the laser wavelength and different laser beam smoothing techniques. Laser intensities required for target acceleration are very high and nonlinear processes are an indispensable part of the laser-plasma interactions. Laser interaction with plasma waves results in stimulated scattering and resonance absorption. Furthermore, coupling of plasma waves to electrons results in fast electron generation and undesired fuel preheating. Control and mitigation of these processes are the subjects of present day research. They are discussed in this review along with reduced models that are designed to represent the microscopic physics in the large scale macroscopic models.

Physics of target implosion

This section describes physical processes related to the target implosion: how the ablation pressure is created, how the fuel is compressed and how the fusion reactions are ignited. The major results consist in the relations between target parameters, ablation pressure and characteristics of the compressed fuel. These relations allow to optimize the efficiency of transfer of the absorbed laser energy to the internal energy of the assembly of the fuel. More detailed descriptions of the hydrodynamic processes in application to

ICF can be found the textbook by Atzeni and Meyer-ter Vehn (2004) and reviews by Brueckner and Jorna (1974), Lindl et al. (2004), and Craxton et al. (2015). Physics principles and schemes of fusion energy production are described in the chapter 12.20 “ICF physics principles”.

Choice of the target and the compression method

To be efficient, the compression of the target must be nearly isentropic. This can be performed by two methods: (i) either launching a converging compression wave to the center of a homogeneous sphere (ii) or by taking the fuel in a form of a thin hollow spherical shell, accelerating it to a certain velocity and letting it converge freely to the center. It is then compressed by the geometric effect of spherical convergence, and its kinetic energy is transformed into the internal energy at the moment of stagnation. The free flight phase is isentropic as the sum of the kinetic energy and of the internal energy is conserved. In both cases the fuel is accelerated by a pressure created by the laser ablation of the external part of the target, called ablator. It also plays the role of a structural element by maintaining the mechanical stability of the target. These two options of possible ICF target architectures are presented in Fig. 1.

In panel A, a gaseous DT fuel is placed inside a spherical shell made of plastic or glass, which acts as ablator and piston. The ablation pressure has to have a special temporal profile so the isentropic compression wave converges to the center of the target, producing there the density and temperature needed for ignition, as described by Kidder (1974). The major advantage of this design is that the target can be maintained at room temperature, but it is very fragile because of a small ablator thickness and high gas pressure inside. Moreover, the ablation pressure needs to be strongly increased at the end of implosion, which imposes strong constraints on the laser system, and the imploded fuel has a cold core and a hot external part. This is not the fuel assembly that is needed for ignition of fusion reactions with a hot core and a cold periphery. Therefore, such targets are used in the physical experiments dedicated to studies of laser absorption and shock formation, but not suited for the energy production.

The second design (panel B) is better suited for the production of energy. Here, the DT fuel is deposited as a thin shell inside the ablator. The residual gas pressure inside could be very low and the target is structurally more stable, but it has to be maintained at a cryogenic temperature of 17 K, because of a very low melting temperature of hydrogen. This design has an advantage of relaxing constraints on the laser power—the shell compression is separated in two stages of acceleration and free flight, and it naturally produces the desired fuel assembly with a hot spot in the center and a cold shell outside. The first step of the shell acceleration can be accomplished by a succession of shocks. This method allows controlling the shell entropy as it discussed in section “Shell acceleration by a succession of shocks.” The second step is an isentropic free flight, and the desired compression is reached by the geometric convergence. The hot spot conditions are defined by the shell implosion velocity and the quantity of gaseous DT inside the shell.

Creation of the ablation pressure by laser

Conversion of the laser pulse energy incident on the target surface into the shell kinetic energy proceeds in several subsequent steps. Firstly, a front part of the laser pulse is absorbed in the outer layer of the target. There, the material is heated, vaporized and transformed in a low density, hot expanding plasma. At the second step, the remaining part of the laser pulse propagates through this plasma and is partially absorbed near its reflection point, called the critical density. For the laser wavelengths in the optical domain, that is, from 0.3 to 1 μm , the plasma critical density is very low, 10–100 times smaller than the solid density. The absorbed laser energy is transported further from this low density hot plasma to the cold solid material by electrons and partially by X-ray radiation. The energy flux arriving on the cold dense material causes its ablation and ejection of the vapors. This is the final step of the laser energy absorption process—the reaction force of ablated vapors creates a pressure on the remaining solid part of the shell.

For the laser intensities of interest for inertial fusion, that is, $I_{\text{las}} \sim 10^{14} - 10^{15} \text{ W cm}^{-2}$, the plasma expansion velocity is about 300 km s^{-1} , and the ablation process becomes quasi-stationary on the nanosecond time scale. It is shown schematically in Fig. 2. Laser energy is absorbed in the hot and underdense corona near the critical surface. The energy flux is then transported

Fig. 1 Target architecture for inertial fusion with gaseous (A) and solid (B) fuel. The external part of target (red) serves as ablator and structural material. A DT may be in a gaseous (blue) or in a solid (green) form.

Fig. 2 Profiles of density (blue) and temperature (red) of the target irradiated by a laser (coming from the right): dashed lines show the radial position of the critical surface, ablation front and shock front. The conduction zone separates the plasma corona to the right and the shocked target to the left.

through the conduction zone to the compressed shell by electrons and photons. It is balanced by the outflow of hot ablated material. Behind the ablation front, there is a shock wave propagating in the solid shell.

Although the fluxes of energy in the laser-irradiated target are equilibrated, this is not true for the mechanical momentum. The pressure of laser radiation is negligible in the ICF conditions. Indeed, assuming that all laser photons are absorbed, the radiation pressure, I_{las}/c , is less than 1 Mbar, while ablation pressure could be 100 times larger.

The ablation pressure can be calculated from the law of energy flux conservation at the target surface. Assume that a fraction η_{abs} of the incident laser radiation is absorbed in the plasma near the critical surface. The absorbed energy is transformed in a plasma outflow ejected from the target with the velocity u , density ρ and temperature T . The conservation of the energy flux reads:

$$I_{\text{abs}} = \eta_{\text{abs}} I_{\text{las}} = \left(\frac{1}{2} \rho u^2 + \frac{5}{2} \rho c_s^2 \right) u \quad (1)$$

The left hand side in this relation presents the absorbed energy flux. The explicit expression for η_{abs} is discussed in section “**Laser propagation in an inhomogeneous plasma**,” devoted to the laser plasma interaction physics. The right hand side presents the flux related to the plasma kinetic energy and enthalpy. Here, $c_s = ((ZT_e + T_i)/m_i)^{1/2}$ is the local ion acoustic velocity, Z is the ion charge, m_i is the ion mass and $T_{e(i)}$ is the electron (ion) temperature. As the thickness of the conduction zone is smaller than the shell radius, we consider here a planar expansion. Then, the mass conservation implies $\rho u = \text{const}$.

While Eq. (1) is valid throughout the conduction zone, there is an additional relation, called the Chapman-Jouguet condition, which follows from the stability of the plasma expansion in the case of localized energy deposition (see [Atzeni and Meyer-ter Vehn \(2004\)](#) for more details). Namely, a transition from subsonic to super-sonic expansion may take place only in the domain where the laser energy is absorbed, that is, near the critical density. Therefore, Eq. (1) has to be complemented by a relation, $u = c_{s,\text{cr}}$ at $\rho = \rho_{\text{cr}}$, and it then takes the following form: $I_{\text{abs}} = 3\rho_{\text{cr}}c_{s,\text{cr}}^3$.

This relation needs one more correction before applying it to the ICF target. In fact, this relation assumes that all absorbed laser energy goes into the conduction zone, which is not the case. The laser corona is not adiabatic, but isothermal, because of a high electron mobility. Therefore, a part of the absorbed laser energy is transported by electrons downstream of the critical density. Therefore, to the expression in the right hand side of this relation one should add the electron heat flux, $\rho_{\text{cr}}c_{s,\text{cr}}^3$, corresponding to the isothermal rarefaction wave in a hot plasma corona. Thus, we obtain the following relation between the absorbed laser energy and the plasma parameters at the critical density:

$$I_{\text{abs}} = 4\rho_{\text{cr}}c_{s,\text{cr}}^2 \quad (2)$$

Here, the critical density is defined by equating the laser frequency, ω_{las} , to the local electron plasma frequency, ω_{pe} (see section “**Laser propagation in an inhomogeneous plasma**” for further details). It can be conveniently expressed as $\rho_{\text{cr}} = n_{\text{cr}}m_i/Z$, where $n_{\text{cr}} = 1.1 \times 10^{21} \lambda_{\text{las}}^{-2} \text{ cm}^{-3}$ is the electron critical density and λ_{las} is the laser wavelength in microns.

Eq. (2) provides a relation of the plasma acoustic velocity at the critical density, $c_{s,\text{cr}} = (I_{\text{abs}}/4\rho_{\text{cr}})^{1/3}$ (it is called also a blowoff velocity, u_{bf}), and, consequently, the ablation rate, $\dot{m}_a = \rho_{\text{cr}}c_{s,\text{cr}}$, to the laser parameters. As the plasma pressure is approximately constant in the conduction zone, one can also evaluate the ablation pressure on the target as a momentum flux, $p_{\text{abl}} \approx \rho_{\text{cr}}c_{s,\text{cr}}^2$. In practical units and for a plastic (CH) plasma one can deduce the following expressions:

$$T_{e,\text{cr}} = 13.7 I_{\text{abs}}^{2/3} \lambda_{\text{las}}^{4/3} \text{ keV}, \quad \dot{m}_a = 3.2 \times 10^5 I_{\text{abs}}^{1/3} \lambda_{\text{las}}^{-4/3} \text{ g s}^{-1} \text{ cm}^{-2}, \quad p_{\text{abl}} = 57 I_{\text{abs}}^{2/3} \lambda_{\text{las}}^{-2/3} \text{ Mbar} \quad (3)$$

where the laser intensity is in units of $10^{15} \text{ W cm}^{-2}$ and a laser wavelength is in microns. Consequently, a laser with such intensity at a wavelength of $\sim 0.3\text{--}0.5 \text{ }\mu\text{m}$ may create pressure on the order of 50–100 Mbar, as needed for an efficient ICF implosion.

It is important to notice that the ablation pressure and the mass ablation rate are inversely proportional to the laser wavelength. The shorter the laser wavelength, the more efficient is the laser action. For this reason and because of a better absorption, the short wavelength laser systems are of major interest for ICF. Such a dependence of the ablation pressure on laser wavelength motivated the indirect drive approach, where the laser radiation is transformed into black-body X-rays in a cavity, known as a *hohlraum*, with a target inside it, see the chapter 12.20 “ICF physics principles” and Lindl et al. (2004). X-ray radiation penetrates deeper into the target and deposits its energy directly in the solid shell. Moreover, black-body radiation is naturally isotropic and thus produces a more homogeneous ablation. A similar indirect drive approach is used in heavy ion inertial fusion, where the energy of an accelerated ion beam is converted into the X-ray radiation which is then directed onto a spherical pellet.

Creation of the ablation pressure with thermal X-rays

X-ray radiation used in the indirect drive approach can be considered as black body radiation. Ablation pressure and mass ablation rate in this case can be also evaluated from Eq. (2). The absorbed energy flux is related to the X-ray black-body temperature, T_X , as $I_{\text{abs}} \approx \sigma_{\text{SB}} T_X^4$, where $\sigma_{\text{SB}} \approx 10^5 \text{ W cm}^{-2} \text{ eV}^{-4}$ is the Stefan-Boltzmann constant. The position of the absorption zone in a stationary regime can be found from the condition that the electrons are in thermal equilibrium with radiation, that is, $T_e = T_X$. Consequently, the plasma blowoff velocity in the absorption zone is known, $u_{\text{bf}} = (ZT_X/m_i)^{1/2}$, and Eq. (2) defines thus the blowoff plasma density, $\rho_{\text{bf}} = \sigma_{\text{SB}} T_X^4 / 4u_{\text{bf}}^3$, which is about 1 g cm^{-3} for the radiation temperature of 300 eV.

From these relations one obtains directly expressions for the mass ablation rate and ablation pressure in practical units:

$$\dot{m}_a = 1.4 \times 10^5 \left(\frac{T_X}{300 \text{ eV}} \right)^3 \text{ g s}^{-1} \text{ cm}^{-2}, \quad p_{\text{abl}} = 170 \left(\frac{T_X}{300 \text{ eV}} \right)^{7/2} \text{ Mbar} \quad (4)$$

So, in order to produce radiation pressure at the level of 100 Mbar, needed for ICF implosion, one has to create black-body radiation with a temperature of 300 eV. This corresponds to the energy density of about 10^5 J cm^{-3} , that is, one needs to deposit a laser energy of about 100 kJ in a cavity of a volume of 1 cm^3 . The plasma density where absorption takes place is comparable to the initial target density, which is favorable for efficient ablation.

Shell acceleration by ablation pressure

Because of shell compressibility, application of an ablation pressure does not lead to an instantaneous acceleration. Ablation pressure creates a shock wave that propagates inside the target. It is shown in Fig. 3 as a zone to the left of the ablation front. Only after the shock traverses the shell, is the latter moving as a whole with a fluid velocity behind the shock u_s . For a material with a polytropic index γ , the velocity D_s of a strong shock and the downstream velocity u_s are defined by the ablation pressure and the shell initial density ρ_0 :

$$D_s = \sqrt{\frac{\gamma + 1}{2} \frac{p_{\text{abl}}}{\rho_0}}, \quad u_s = \frac{2}{\gamma + 1} D_s \quad (5)$$

In the particular case of a mono-atomic gas with $\gamma = 5/3$, the shock velocity is $D_s = 1.15 (p_{\text{abl}}/\rho_0)^{1/2}$ and $u_s = 0.87 D_s$.

Fig. 3 Target acceleration shown in mass coordinates: light red—plasma corona, yellow—conduction zone, cyan—cold shell, light blue—compressed target behind the first shock, rose—rarefaction wave, green—target compressed by the second shock. Red line shows the trajectory of critical surface, magenta—trajectory of the ablation front, blue—trajectories of the shock and rarefaction waves.

One can make a distinction between two regimes of laser-target interaction. If the shell thickness, d_s , is sufficiently large and laser energy deposition ends before the shock crosses the shell, the latter is compressed but does not move. Otherwise, if the laser pulse duration is longer than d_s/D_s , the target as a whole gains a velocity u_s . This latter regime is the one of interest for ICF.

The target acceleration scheme is presented in Fig. 3. The first shock propagates with a velocity, D_{s1} , and arrives at the rear shell interface at the time t_s . It is reflected there and propagates back as a rarefaction wave. The shell behind the first shock is already compressed and accelerated to the velocity, u_{s1} , defined by the ablation pressure. When the rarefaction wave arrives at the ablation front it is reflected as a second shock. It propagates through the shell with the velocity $D_{s2} > D_{s1}$, compresses it and accelerates the shell once more to the velocity $u_{s1} + u_{s2}$. This process of consecutive propagation of the shock and the rarefaction waves across the shell repeats itself several times. After each shock reflection the shell gains an additional velocity. So the shell acceleration proceeds as a step-like process. If the shell is sufficiently thin and the shocks are crossing it many times, one can consider the interaction as in a continuous acceleration of the shell as a whole. This is described by a rocket model presented in section “Shell acceleration by ablation pressure”. The acceleration ends in the moment when the ablation front reaches the rear side of the shell.

Shell acceleration by a succession of shocks

The target acceleration is a non-isentropic process. The shock dissipates its energy and produces entropy in the compressed material. The larger the shock amplitude, the more entropy is injected in the fuel. Thus, the first shock defines a large part of the entropy of the shell. However, material compression in a shock is limited to a factor $(\gamma + 1)/(\gamma - 1)$, which is 4 for a mono-atomic gas, where $\gamma = 5/3$. That is much less than one needs for the ICF implosion. Thus, it is important to understand how one can accelerate a shell and compress it to high densities without injecting too much entropy.

Suppose that the initial state of the shell is characterized by a pressure p_0 and a density ρ_0 . If it would be compressed by an external pressure, p isentropically, its density will increase according to the power law:

$$\rho = \rho_0 \left(\frac{p}{p_0} \right)^{1/\gamma} \quad (6)$$

However, to realize such a compression, the pressure should be applied to all material at the same time. Instead, the ablation pressure is applied to the edge of the shell. It produces a shock, which deposits in the material a certain quantity of energy, and compression in a shock is described by the Rankine-Hugoniot relation:

$$\rho = \rho_0 \frac{(\gamma + 1)p + (\gamma - 1)p_0}{(\gamma - 1)p + (\gamma + 1)p_0} \quad (7)$$

The curves described by Eqs. (6), (7) departing from the same point are shown in Fig. 4. The isentropic curve (red) allows an arbitrary strong compression depending on the applied pressure. Conversely, the Rankine-Hugoniot relation (black) limits the maximum compression by a factor $(\gamma + 1)/(\gamma - 1)$. Thus, one shock cannot compress the target more than a factor of 4. (A stronger compression is possible in radiatively cooling shocks, but this is not suitable for ICF targets that use low atomic number materials.)

A much more efficient compression can be achieved with a succession of several shocks. Fig. 4 shows a comparison between the compression with one shock with a pressure jump, $p/p_0 = 216$, and a succession of three shocks of an equal strength, $p_1/p_0 = p_2/p_1 = p_3/p_2 = 6$, with the same total pressure jump, $p_3/p_0 = 6^3 = 216$. Each shock creates a smaller compression, $\rho_1/\rho_0 = \rho_2/\rho_1 = \rho_3/\rho_2 = 2.5$, but a sequence of three shocks allows the achievement of a much higher compression of $\rho_3/\rho_0 = 2.5^3 \approx 15.6$, compared to 3.9 in the single shock case, while maintaining the same overall pressure jump.

This difference is due to a smaller target entropy in the second case. It can be characterized by a dimensionless factor called adiabat, $\alpha = p_0^*/p_0$. Here, p_0^* is the initial pressure of the isentrope corresponding to the final state p_3, p_3 . It is shown with a dashed red line

Fig. 4 Compression diagram of a plane target described as a mono-atomic gas: red—isentropic compression from the initial pressure; dashed red—isentrope corresponding to the initial pressure $p_0^* = 2.2p_0$; black—Rankine-Hugoniot adiabat; blue, green, purple—compression with a sequence of three shocks with a strength $p_{i+1}/p_i = 6$.

in Fig. 4. Adiabatic characterizes how much entropy has been introduced into the material downstream of the shocks. In our example with three shocks, the initial pressure corresponding to the new isentrope is 2.2 times higher than p_0 , and therefore the succession of three shocks increases the adiabat by a factor of $\alpha = 2.2$. This should be compared with the factor 22 of the entropy increase in the case of a single shock with the same pressure jump. For the ICF target compression, the shell initially is cold and p_0 corresponds to the pressure of degenerate electrons. Thus, α characterizes how much entropy is introduced by the shocks into the shell compared to the ideal isentropic compression. One says that a sequence of three shocks puts the shell on the adiabat $\alpha = 2.2$.

Fig. 4 shows that each subsequent shock has a higher pressure and correspondingly propagates faster than the preceding one. So, it is possible to adjust the launch time of each subsequent shock in such a way that all of them merge at the rear side of the shell. This condition corresponds to the most efficient shell acceleration with the minimum deposited entropy. Thus, the timing of the shock launch is the most important adjustable parameter of the implosion process. It depends on the laser intensity and wavelength, the thickness and the material of the shell, and it is chosen by using theoretical models and numerical simulations.

Rocket model

The rocket model describes a thin shell acceleration as a continuous process, considering it as a rigid object with a variable mass. We, therefore, neglect the time that it takes the shock to cross the target, assuming that the acceleration process takes a longer time. Although this is not exactly the situation in the ICF targets, the rocket model is a convenient approximation that describes the major features of the process.

Shell acceleration is described by the laws of conservation of mass and momentum in a system containing a solid target and plasma ejecta. The model is similar to the equations describing the acceleration of a rocket. In the case of a planar foil, this equation applies to a unity of surface with the areal mass M_σ :

$$\frac{d}{dt}(M_\sigma U_{\text{imp}}) = \dot{m}_a(u_{\text{bf}} - U_{\text{imp}}) \quad (8)$$

Here, the right hand side describes the change of the momentum of the target, $M_\sigma U_{\text{imp}}$, due to ejection of a plasma with a relative velocity $u_{\text{bf}} - U_{\text{imp}}$. A decrease of the target mass is defined by the ablation rate (3):

$$dM_\sigma/dt = -\dot{m}_a \quad (9)$$

Excluding the time derivative from the first equation by using the mass conservation, we obtain a relation between the target velocity and its mass, $dU_{\text{imp}}/dM_\sigma = -u_{\text{bf}}/M_\sigma$. Assuming a constant blowoff velocity, this equation can be integrated giving the target velocity as a logarithmic function of the mass, which decreases linearly with the time:

$$M_\sigma = M_{\sigma 0} - \dot{m}_a t, \quad U_{\text{imp}} = -u_{\text{bf}} \ln \frac{M_{\sigma 0}}{M_\sigma} \quad (10)$$

A negative sign in the second equation indicates that the target is accelerated in a direction opposite to that of the ejection of vapors. The maximum time of the acceleration process depends on the target thickness, $t_{\text{acc,max}} = M_{\sigma 0}/\dot{m}_a$, where $M_{\sigma 0}$ is the initial target areal mass.

According to Eq. (10), one can accelerate target to an arbitrary large velocity, but the efficiency of this process depends on the ratio of the residual payload to the initial mass $X = M_\sigma/M_{\sigma 0}$. The mechanical efficiency of the acceleration process can be defined as the ratio of the kinetic energy of the remaining solid part of the shell, $\frac{1}{2}M_\sigma U_{\text{imp}}^2$ to the kinetic energy of ejecta:

$$\eta_{\text{acc}} = \frac{M_\sigma U_{\text{imp}}^2}{(M_{\sigma 0} - M_\sigma) u_{\text{bf}}^2} = \frac{X \ln^2 X}{1 - X}. \quad (11)$$

It is shown in Fig. 5A. The maximum efficiency of 65% is achieved when 80% of the initial mass is ablated. In that particular case the target speed is $\ln 5 = 1.6$ times larger than the ejecta velocity.

Implosion of a spherical shell

The rocket model can be readily modified to account for the spherical geometry. The velocity of a shell of a mass M , radius R and thickness $\Delta R \ll R$ is defined as $U_{\text{imp}} = dR/dt$. Then Eqs. (8), (9) take the following form:

$$\frac{d}{dt}(MU_{\text{imp}}) = 4\pi R^2 \dot{m}_a(u_{\text{bf}} - U_{\text{imp}}), \quad \frac{dM}{dt} = -4\pi R^2 \dot{m}_a \quad (12)$$

Excluding the time derivative from these two equations, we find again a logarithmic relation between the shell velocity and the mass, (10). That leaves us with one differential equation relating the shell mass to the radius:

$$\ln X \frac{dX}{dR} = -4\pi R^2 \frac{\dot{m}_a}{u_{\text{bf}} M_0} \quad (13)$$

It depends on a dimensionless parameter:

Fig. 5 (A) Mechanical efficiency of a planar foil acceleration by the ablation pressure, η_{acc} (11) as a function of the residual mass, $X = M_r/M_{r0}$. (B) Radius of a spherical shell accelerated by the ablation pressure as a function of the residual mass, X , for the value of implosion parameter (14) $B_r = 1.5$ (1, red) and $B_r = 3.5$ (2, blue). (C) Parameters of an imploding spherical shell at the moment when its radius, R , decreased two times with respect to the initial value, R_0 , as a function of the implosion parameter B_r : energetic efficiency (blue), ablated mass (red) and shell velocity (green).

$$B_r = \frac{4\pi\dot{m}_a R_0^3}{u_{\text{bf}} M_0} = \frac{\dot{m}_a R_0}{\rho_1 u_{\text{bf}} \Delta R_1} \quad (14)$$

Here, we accounted for the relation between the shell mass and its thickness, $M_0 = 4\pi\rho_0 R_0^2 \Delta R_0$, and for the fact that the acceleration starts after the first shock crosses the shell and compresses it from the initial value, ρ_0 , to the value, ρ_1 , while its areal mass remains the same, $\rho_0 \Delta R_0 = \rho_1 \Delta R_1$. According to section “**Rocket model**”, the maximum compression in the case of an ideal mono-molecular gas is 4, but in real experiments the solid shell is compressed by $\rho_1/\rho_0 \approx 2 - 3$ times.

Parameter B_r has a simple interpretation as a ratio between the time of the shell collapse to the center and the burnthrough time. The solution of Eq. (14) gives an implicit relation between the residual mass of the shell and its radius

$$1 + X(\ln X - 1) = \frac{B_r}{3} \left(1 - \frac{R^3}{R_0^3} \right) \quad (15)$$

The left hand side term in this equation is limited in the interval between 0 and 1. The term in parenthesis in the right hand side is limited to the same interval. Thus, the value of B_r defines the final state of the acceleration process. The dependence of the position of the shell as a function of the shell mass, $R(X)$, is presented in Fig. 5B. For $B_r < 3$, the shell collapses in the center before it is completely ablated. Conversely, for $B_r > 3$, the target is too thin, or the ablation rate is too high, so the target mass goes to zero before the shell reaches the center. Thus, the value $B_r = 3$ separates two regimes of shell acceleration.

It can be seen in Fig. 5B that a notable shell acceleration occurs when the shell radius decreases by at least a factor of 2. At that time, acceleration can be stopped and the shell will continue its implosion in free flight under its own inertia. Fixing the shell convergence at $R_f/R_0 = 1/2$, one can solve the system (13) numerically and obtain the efficiency of the implosion as a function of the shell parameter B_r , shown in Fig. 5C. The range $0.5 < B_r < 2.5$ corresponds to the most efficient implosion. The limit $B_r < 0.5$ corresponds to a very light target, and the case $B_r > 2.5$ to a very massive target. The value $B_r = 1.6$ corresponds to the maximum hydrodynamic efficiency of 65%. In that case the residual mass is 20% of the initial mass, and, according to Eq. (10), the shell implosion velocity $U_{\text{imp}} = 1.6 u_{\text{bf}}$.

Practically, it is too risky to vaporize 80% of the total mass. The shell becomes too fragile and can be easily destroyed by hydrodynamic instabilities. Aiming on a convergence factor of the order of 10, it is reasonable to vaporize not more than half of the initial shell mass. As a consequence, the implosion parameter in the direct drive scheme cannot be much bigger than $B_r = 0.5$. This, however, reduces the acceleration efficiency to about 50%. The shell speed is then only $0.7 u_{\text{bf}}$.

From this analysis we can obtain a practical formula for the shell implosion velocity. According to Fig. 5C, shell velocity depends approximately linearly on the implosion parameter B_r . Therefore, according to Eq. (14), $U_{\text{imp}} \approx B_r u_{\text{bf}} = \dot{m}_a R_0 / \rho_1 \Delta R_1$. This formula can be further simplified recalling that the ablation rate is related to the ablation velocity, $D_a = \dot{m}_a / \rho_1$. The parameter $A_{\text{if}} = R_0 / \Delta R_1$ is called the shell in-flight aspect ratio. It is different from the shell initial aspect ratio, $A_0 = R_0 / \Delta R_0$, because of the shell compression in the first shock. Using the definition of the aspect ratio, we obtain a simple relation between the implosion and ablation velocities:

$$U_{\text{imp}} = D_a A_{\text{if}} \quad (16)$$

Thus, one can increase the implosion velocity by an appropriate choice of the shell aspect ratio. It depends on the initial aspect ratio and the amplitude of the first shock. The latter is limited by the condition on the shell entropy and adiabat parameter. A cold shell can be assimilated to a degenerate electron gas and its pressure can be estimated as a Fermi pressure, $p_F = (3\pi^2)^{2/3} \hbar^2 n_e^{5/3} / 5m_e$ Landau and Lifshitz (1980), where $\hbar$ is the Planck constant and m_e is the electron mass. For the DT gas of a density ρ expressed in g cm^{-3} , the Fermi pressure reads $p_F = A_F^{5/3} \text{ Mbar}$, with $A_F = 2.16$. The density of solid DT is 0.25 g cm^{-3} and the corresponding Fermi pressure is $\sim 0.2 \text{ Mbar}$. Assuming a compression factor of ~ 3 and an in-flight adiabat parameter $\alpha_{\text{if}} = 2$, the first shock pressure is 1.3 Mbar . According to Eq. (3), that ablation pressure corresponds to relatively low laser intensities $\sim 3.5 \times 10^{12} \text{ W cm}^{-2}$. By contrast, in order to achieve implosion velocities of about 300 km s^{-1} needed for fuel ignition, according to Eq. (16), one needs

more than two orders of magnitude higher laser intensities. This example shows that a careful choice of the laser pulse temporal profile is very important for an efficient implosion.

Mechanical efficiency as defined by the rocket model, Eq. (11) and Fig. 5, accounts only for the kinetic energy of the blowoff plasma. However, as is discussed in section “Creation of the ablation pressure by laser”, the internal energy of the ejected plasma is larger than its kinetic energy. According to Eqs. (1), (2), in the Chapman-Jouguet point, the plasma density is equal to the critical density, ρ_{cr} , and its hydrodynamic velocity, u_{bf} , is equal to the ion acoustic velocity, $c_{s,cr}$. Thus, the total plasma energy, $(M_0 - M)\left(\frac{1}{2}u_{bf}^2 + \frac{3}{2}c_{s,cr}^2\right) = 2(M_0 - M)u_{bf}^2$, is four times its kinetic energy. Consequently, the hydrodynamic efficiency of the ablative acceleration is four times smaller than the mechanical efficiency, and is given by:

$$\eta_{hydro} = \frac{MU_{imp}^2}{MU_{imp}^2 + 4(M_0 - M)u_{bf}^2} = \frac{\eta_{acc}}{4 + \eta_{acc}} \quad (17)$$

The maximum mechanical acceleration efficiency of 65% obtained in the rocket model corresponds thus to only 16% of the total hydrodynamic efficiency. In reality, there are additional losses related to: (i) incomplete laser energy absorption; (ii) vaporization and ionization of ejecta and (iii) radiation cooling of expanding plasma, which further reduce the achievable level of hydrodynamic efficiency. In practice its value is less than 8%.

Shell deceleration and hot spot formation

After compression by the first shock and further acceleration by the ablation pressure according to the rocket model, the shell enters the coasting phase: a free flight toward the center. As is discussed above, it is reasonable to end acceleration at the moment when shell radius decreases by approximately a factor of 2, from R_0 to $R_1 \approx \frac{1}{2}R_0$. Assuming a constant in-flight aspect ratio, the fuel density at the acceleration phase is increased by a factor of $(R_0/R_1)^2 \approx 4$. Moreover, the shell is already compressed before the deceleration phase by a factor of $\sim 2-3$ in the first shock. Therefore, the shell is compressed by a factor of about 10 at this stage, $\rho_1 \approx 10\rho_0$. Accounting also for the increase of adiabat by a factor of approximately 2, the shell pressure, $p_1 \approx \alpha A_F \rho_1^{5/3}$, is increased by more than a factor of 100 to $\sim 30-50$ Mbar. Although the acceleration is terminated, the laser pulse intensity has to be maintained at a constant level in order to prevent the shell from expanding.

The shell initial deceleration phase can be described by assuming the pressure to be homogeneous across the shell. The free flight is an isentropic process and, therefore, the kinetic energy gained by the shell during acceleration is gradually converted into its internal energy as the shell decelerates. This process is described by a dynamic equation:

$$M_{sh} dU_{sh}/dt = -4\pi R_{sh}^2 (p_{sh} + p_h) \quad (18)$$

where $U_{sh} = dR_{sh}/dt$ is the shell velocity and M_{sh} is the shell mass, which is approximately constant at this phase. The right hand side accounts for the shell internal pressure, which is considered as a partially degenerate electron gas, $p_{sh} = \alpha_{if} A_F \rho_{sh}^{5/3}$, and the pressure of the DT gas inside, which can be considered as an ideal classical gas, $p_h = 2n_i T_h$, assuming equal electron and ion temperatures.

Let us first consider an empty shell. It slows down under its own internal pressure and stops at a minimum radius, R_c , when the pressure work, $4\pi \int R_{sh}^2 p_{sh} dR$, is equal to its initial kinetic energy, $\frac{1}{2} M_{sh} U_{imp}^2$. Assuming the shell thickness and adiabat are constant during the flight, the shell density is inversely proportional to the square of the radius, then one can express the maximum converging factor $C_R = R_1/R_c$ as follows:

$$C_R = \left(1 + M_{sh} U_{imp}^2 / 4 A_{if} \mathcal{E}_{sh0}\right)^3 \quad (19)$$

where $\mathcal{E}_{sh0} = 6\pi p_1 R_1^3 / A_{if}$ is the shell internal energy at the end of the acceleration phase. According to this expression, the shell compression is proportional to the cube of the ratio of shell kinetic and internal energy.

Hot spot energy balance

In the ICF schemes with ignition from a central hot spot, the internal gas pressure dominates the shell pressure at the end of implosion. The hot spot is created during implosion, when the first shock exits the shell and enters the gas inside. Because of a low gas density, $\rho_g \sim 0.1 \text{ mg cm}^{-3}$, the transmitted shock pressure decreases by a factor $\rho_g/\rho_{sh} \sim 10^{-3}$, but it increases as the shock converges to the target center. The reflection of a spherical shock is described by a self-similar solution of the equations of ideal hydrodynamics found by Guderley (1942), see also Atzeni and Meyer-ter Vehn (2004). According to this solution, after reflection, the DT gas pressure, p_{h0} , increases by a factor of 40 to about 0.1 Mbar and the gas is heated to a temperature of about 100 eV. Subsequent hot spot evolution takes place during the implosion phase. For simplicity, in the following estimates the shell is considered as a rigid piston.

The hot spot dynamics are described by the equation of energy conservation. The gas implosion is subsonic as the implosion velocity is small compared to the acoustic velocity in the hot spot. Consequently, we may account only for the gas internal energy, $\frac{3}{2} p_h V_h$, with p_h being homogeneous across the hot spot of a volume $V_h = \frac{4}{3} \pi R_{sh}^3$.

There are two sources of increase of the hot spot energy: the work performed by the piston, $-4\pi R_{sh}^2 p_h U_{sh}$, and the energy released in fusion reactions and deposited in the hot spot. There is also a channel of energy loss: bremsstrahlung emission. The shell is typically transparent for the fusion neutrons and X-ray photons. Consequently, the energy equation for the hot spot takes the form:

$$(3/2)d(p_h V_h)/dt + 4\pi R_{sh}^2 p_h U_{sh} = (W_\alpha - W_{br})V_h \quad (20)$$

The rate of bremsstrahlung emission, W_{br} , is proportional to the product of electron and ion densities, $n_e = n_i$, and increases as the square root of temperature. For a DT plasma it can be written as

$$W_{br} = 5.3 \times 10^{-31} n_e^2 T_e^{1/2} \text{ W cm}^{-3} \quad (21)$$

where plasma density, n_e , is in units of cm^{-3} and temperature is in keV, see [NRL \(2007\)](#).

Assuming equipartition of deuterium and tritium with densities, $n_D = n_T = \frac{1}{2}n_e$, the rate of energy release by α -particles having energy, $\varepsilon_\alpha = 3.5$ MeV, can be written as $W_\alpha = \frac{1}{4}n_e^2 \varepsilon_\alpha \langle \sigma_{DT} v \rangle$. The last term in this expression is the rate of DT reactions, which depends on the ion temperature, T_i . Near the ignition threshold, in the temperature range between 8 and 20 keV, it can be interpolated as a quadratic function, $\langle \sigma_{DT} v \rangle \approx 1.1 \times 10^{-18} T_i^2 \text{ cm}^3 \text{ s}^{-1}$, where T_i is keV. Consequently, the energy release rate can be presented in the form:

$$W_\alpha \approx 1.5 \times 10^{-31} n_e^2 T_i^2 \text{ W cm}^{-3} \quad (22)$$

where density is in the units of cm^{-3} and temperature in keV.

From these expressions one can obtain several conclusions. Firstly, by comparing the two terms in the right hand side of Eq. (20), we find the minimum hot spot temperature needed for ignition fusion reactions. The condition $W_\alpha > W_{br}$ defines the minimum temperature, $T_{\min} \approx 4$ keV. Secondly, above this temperature, the rate of fusion reactions increases so rapidly that one can neglect the radiation losses and analyze Eq. (20) without the loss term. Then, noting that the product $n_i T_i$ is equal to $\frac{1}{2} p_h$, assuming equal temperatures of electrons and ions, the energy balance in the hot spot takes the form:

$$dp_h/dt = -5p_h U_{sh}/R_{sh} + S_\alpha p_h^2 \quad (23)$$

where $S_\alpha = 0.1 \text{ ns}^{-1} \text{ Gbar}^{-1}$. It is important to note that this equation does not contain the terms of energy exchange between the hot spot and the shell. This is explained by the fact that energy transferred by electrons and α -particles to the shell is recovered as the flow of ablated mass to the hot spot. Thus, the mass of the hot spot increases with time, but it does not have an effect on the hot spot pressure, which depends only on the compression work and the fusion energy production, see [Betti et al. \(2002\)](#).

The two terms in the right hand side of Eq. (23) represent the piston work and the fusion energy production. The piston work is reversible: the hot spot pressure increases as the fifth power of compression and then decreases. By contrast, the fusion energy production is irreversible: if this term dominates, the pressure increases explosively, $p_h = p_{h0}/(1 - p_{h0} S_\alpha t)$. This explosive behavior can be identified as ignition. Thus, by comparing the two terms in the right hand side we can define the ignition threshold as

$$p_{h,ig} \approx 5U_{imp}/R_c S_\alpha \quad (24)$$

Here, for the estimate of implosion time we consider the shell implosion velocity and its radius at the stagnation. For typical values of $U_{imp} \sim 300 \text{ km s}^{-1}$ and $R_c \sim 50 \text{ }\mu\text{m}$, the ignition pressure is on the order of 300 Gbar. This corresponds to the hot spot energy of a few tens of kJ, that is, about 20–40% of the shell kinetic energy. The shell compression can be obtained by solving Eqs. (18), (23) while neglecting the shell internal pressure and fusion reactions:

$$C_R = \left(1 + M_{sh} U_{imp}^2 / 2\mathcal{E}_{h0}\right)^{1/2} \quad (25)$$

where $\mathcal{E}_{h0} = 2\pi p_{h0} R_1^3$ is the initial energy of the hot spot.

The pressure in the left hand side of expression (24) can be estimated as the initial hot spot pressure, p_{h0} , multiplied by the compression ratio to the fifth power. Thus, Eq. (24) can be represented as a condition on the initial hot spot pressure and compression ratio:

$$p_{h0} > 5U_{imp}/R_1 S_\alpha C_R^5 \quad (26)$$

In addition, we need to impose the condition of validity of Eq. (23), namely, that the hot spot temperature is sufficiently high and that the T_i^2 dependence of the fusion reaction rate applies. This means that α -particles have to deposit a significant fraction of their energy, f_α , inside the hot spot.

The factor f_α depends on the ratio, $\tau_\alpha = l_\alpha/R$, of the α -particle stopping range, l_α , to the hot spot radius, R . In the temperature domain of interest, the stopping range can be expressed as $l_\alpha \approx 0.025 T^{5/4} / \rho_h \text{ cm}$, where the plasma temperature is in keV and density is in g cm^{-3} . The fraction of fusion energy deposited in the hot spot can be interpolated as proposed by [Krokhin and Rozanov \(1973\)](#) and [Gus'kov et al. \(1975\)](#):

$$f_\alpha = \begin{cases} 1.5\tau_\alpha - 0.8\tau_\alpha^2, & \text{for } \tau_\alpha < 0.5, \\ 1 - 0.25\tau_\alpha^{-1} - 0.00625\tau_\alpha^{-3}, & \text{for } \tau_\alpha \geq 0.5. \end{cases} \quad (27)$$

Consequently, the condition $\tau_\alpha \geq 0.5$ is needed for achieving ignition.

Moreover, the initial mass of DT gas is not sufficient to achieve ignition. The hot spot mass is provided by the shell internal ablation under the electron energy flux. The mass ablation rate can be evaluated similarly to the X-ray-driven ablation discussed in section ["Creation of the ablation pressure with thermal X-rays"](#) by equating the energy flux entering the solid shell to the energy

carried with the ablated plasma, $4\rho_{bf}u_{bf}^3$. The only difference from Eqs. (2), (4) is that the energy flux is provided by the electron heat conduction and α -particles. The electron heat flux, $q_e = -\kappa_{SH}dT/dR$, can be estimated as $\approx \kappa_{SH} T_h/R_{sh}$, where

$$\kappa_{SH} = 3.24n_e v_{te}^2 / \nu_{ei} = \kappa_{e0} T_h^{5/2} \quad (28)$$

is the Spitzer heat conductivity, with $v_{te} = (T_e/m_e)^{1/2}$ being the electron thermal velocity and ν_{ei} the electron-ion collision frequency. For a DT plasma and taking a value 5 for the Coulomb logarithm, $\kappa_{e0} \approx 1.2 \times 10^{28} \text{ cm}^{-1}\text{s}^{-1}\text{keV}^{-5/2}$. Estimating then the blowoff velocity as $u_{bf} \approx (T_h/m_i)^{1/2}$, we obtain the following expression for the mass ablation rate: $\dot{m}_e = \rho_{bf}u_{bf} \approx 0.25m_i\kappa_{e0}T_h^{5/2}/R_{sh}$.

Similarly, the energy flux of α -particles can be estimated as $(1-f_\alpha)W_\alpha V_h/S_h$, and the corresponding mass ablation rate reads: $\dot{m}_\alpha \approx 0.25(1-f_\alpha)W_\alpha m_i T_h/R_{sh}$.

At the shell deceleration stage, the electron driven ablation dominates. The hot spot temperature can be related to the pressure and mass: $T_h = 2\pi m_i p_h R_{sh}^3/3M_h$, and, assuming that that hot spot pressure evolves adiabatically, $p_h = p_{h0}(R_1/R_{sh})^5$, the equation for the hot spot mass, $dM_h/dt = 4\pi R_{sh}^2 \dot{m}_e$ can be expressed as follows:

$$\frac{dM_h}{dt} = \pi \kappa_{e0} m_i^{7/2} \frac{\mathcal{E}_{h0}^{5/2} R_1^5}{M_h^{5/2} R_{sh}^4} \quad (29)$$

As the shell trajectory $R_{sh}(t)$ is known from Eq. (18), Eq. (29) can be readily integrated, thus providing the hot spot mass at stagnation, M_{hc} :

$$M_{hc} \approx m_i (\pi \kappa_{e0} R_1^2 / U_{sh})^{2/7} \mathcal{E}_{h0}^{5/7} C_R^{6/7}$$

A typical value of hot spot mass is on the order of 10 μg , that is, about 1% of the total fuel mass. Similarly, one obtains expressions for the hot spot areal density and hot electron temperature at stagnation:

$$\rho_h R_c \approx M_{hc} C_R^2 (3/4\pi R_{sh0}^2), \quad T_h \approx (m_i/M_{hc}) C_R^2 \mathcal{E}_{h0}$$

By using these two expressions along with Eq. (25) for the compression ratio, one can present the two ignition conditions, Eq. (26) and $\tau_a \gtrsim 0.5$, as two criteria on the shell implosion velocity. In practical units they read:

$$\left(\frac{M_{sh}}{1 \text{ mg}}\right)^{1/2} \left(\frac{U_{imp}}{300 \text{ km s}^{-1}}\right)^{4/5} > \left(\frac{R_1}{1 \text{ mm}}\right)^{13/10} \left(\frac{p_{h0}}{1 \text{ Mbar}}\right)^{3/10} \quad (30)$$

$$\left(\frac{M_{sh}}{1 \text{ mg}}\right)^{1/2} \left(\frac{U_{imp}}{300 \text{ km s}^{-1}}\right)^{11/20} > \left(\frac{R_1}{1 \text{ mm}}\right)^{5/4} \left(\frac{p_{h0}}{1 \text{ Mbar}}\right)^{1/4} \quad (31)$$

These analytic estimates provide the values of characteristic parameters that must be attained at the acceleration stage in order to achieve ignition from the hot spot. They are confirmed with more detailed numerical simulations.

Burn-wave propagation in a cold shell

As soon as ignition conditions are achieved in the hot spot, the hot spot pressure and temperature increase and a strong shock is launched into the shell. Behind the shock, the hot spot energy and mass increase because of energy released in fusion reactions and enhanced shell internal ablation driven by an energy flux of α -particles escaping the hot spot. The burn front velocity is typically smaller than the shock velocity, thus the burn time is defined by the time of the shell confinement, that is, the time of shock propagation across the shell, $\Delta t_{sh} = \Delta R_{sh}/D_s$ and the time of rarefaction wave propagation backwards from the shell edge to the burn front, $\Delta t_{rw} = \frac{1}{4}\Delta R_{sh}/c_{sh}$. Here, $D_s \approx \sqrt{p_h/\rho_{sh}}$ is the shock velocity and $c_{sh} \approx \sqrt{p_h/4\rho_{sh}}$ is the acoustic velocity in the shocked shell compressed by approximately a factor of 4 in the shock.

The dynamics of the burning hot spot is described by equations of energy and mass conservation similar to Eqs. (20), (29), with the difference that one has to account for the work performed by the shock and for the ablation due to the α -particle energy flux. The kinetic energy of the hot spot can be neglected because of its subsonic expansion. Consequently, the hot spot dynamic equations read:

$$(3/2)d(p_h V_h)/dt = W_\alpha V_h - 4\pi R_h^2 p_h u_s \quad (32)$$

$$dM_h/dt = (1-f_\alpha)m_i W_\alpha V_h/T_h \quad (33)$$

Here, $u_s = \frac{3}{4}D_s \approx dR_h/dt$ is the fluid velocity behind the shock and we neglected the bremsstrahlung losses and the electron heat flux.

This system of equations has been analyzed by Atzeni and Caruso (1984) and more recently by Christopherson et al. (2018). If fusion reactions are ignited, the temperature in the hot spot rises quickly to a value of $T_{\max} \approx 40\text{--}50 \text{ keV}$, corresponding to the maximum of the DT reaction rate. This value defines the pressure in the burning plasma and the burn time, $t_b \approx \Delta t_{sh} + \Delta t_{rw}$, which is proportional to the shell thickness. Its typical value is about 100 ps.

Knowing the plasma temperature and the burn time, one can also evaluate the fraction of the fuel that can be burnt during the confinement time: $\Phi_b \approx W_\alpha V_{sh}(R_{sh}/D_s)/(\epsilon_\alpha \rho_{sh} V_{sh}/2m_i)$. As the fusion rate is proportional to the square of the fuel density, the burn fraction is proportional to the shell areal density:

$$\Phi_b = \rho_{sh} R_{sh} / H_b$$

where $H_b \approx 8m_i D_s / \langle \sigma_{DT} v \rangle \approx 7 \text{ g cm}^{-2}$. Such a high value of the fuel areal density is very difficult to achieve. The present day designs aim at shell areal densities of about $1.5\text{--}2 \text{ g cm}^{-2}$, which correspond to a fuel compression of more than a factor of 1000. Correspondingly, the expected burn fraction is on the order of 20–30%. The physics of target implosion and burn is demonstrated in the numerical simulation presented in the next section.

Numerical simulations of an ICF target

Numerical simulations of target implosion are based on the hydrodynamic model considering the plasma as a single species, multi-material, two-temperature fluid. The equations of ideal hydrodynamics present the basic framework of the model. They are completed with modules describing all the physics involved in the ICF process. The following physical effects are typically included in the model: (i) laser energy deposition in plasma corona; (ii) realistic equations of state; (iii) electron and ion heat conduction; (iv) radiation transport with tabulated opacities; (v) generation of spontaneous magnetic fields and their effect on transport coefficients; and (vi) fusion reactions and α -particle energy transport. The equations are solved on an unstructured grid with Lagrangian or Eulerian solvers in one-, two- or three-dimensional geometry depending on the problem considered.

Theoretical estimates of the target implosion are illustrated here with numerical simulations conducted with the radiation hydrodynamic code CHIC, see Ribeyre et al. (2008). We consider a directly driven “all DT” target containing a very thin plastic shell of $3 \mu\text{m}$, to ensure the mechanical support, and a DT layer with a thickness of $211 \mu\text{m}$. The total fuel mass is 0.59 mg , external radius is $1047 \mu\text{m}$ and gas density is 0.1 mg cm^{-3} (see Fig. 1B). The external part of this DT shell is used as an ablator and the internal part as a fuel. So the effective fuel mass is about a half of the initial mass, that is, 0.3 mg . This target produces in the numerical simulation a thermonuclear energy of 19.5 MJ , with an energy gain of 150.

The laser pulse shape shown in Fig. 6A is chosen in such a way that it creates the level of pressure needed for acceleration of the shell with a desired value of the in-flight shell adiabat, $\alpha_{if} \approx 1$. The formulas for the ablation pressure and ablation mass rate (3) allow definition of the necessary laser intensities and powers. We consider a laser wavelength of 351 nm (third harmonic of the Nd:glass laser) and a coefficient of absorption, $\eta_{abs} \approx 70\%$. The first shock with an amplitude of 2.4 Mbar , is created by a pre-pulse (a “foot”) with an intensity $4 \times 10^{12} \text{ W cm}^{-2}$, corresponding to a laser power of 0.6 TW . The duration of the pre-pulse, $t_1 \approx 4 \text{ ns}$, is defined by the time needed for the first shock to cross the shell. The second shock, that propagates faster than the first, catches the first one at the inner edge of the shell. This allows maintenance of a low adiabat in the fuel and preheating the gas inside the shell. The total energy of the laser pulse is 134 kJ , and the absorbed energy is 92 kJ .

The rising part of the pulse in the time interval between 4 and 8 ns is dedicated to acceleration of the shell to the implosion speed, $U_{imp} \approx 240 \text{ km s}^{-1}$. The ablation pressure is rising gradually to 40 Mbar , which corresponds to increasing laser intensity to the level of $3 \times 10^{14} \text{ W cm}^{-2}$ and the pulse power to 40 TW . This level is maintained during the implosion time, which is approximately 3.5 ns in the present example. Fig. 6B shows the implosion diagram—the trajectories of the fluid elements. Initially, all the mass of the target is distributed homogeneously in the interval $0.833 < R < 1.044 \text{ mm}$. Upon the laser pulse arrival, the outer cells are ablated and shifted outwards. The shock generated by the pre-pulse ablation pressure is moving inwards with a velocity of $\sim 30 \text{ km s}^{-1}$, and at time $t_2 = 7 \text{ ns}$ it arrives at the rear side of the shell. Starting from this moment, the shell as a whole is accelerated by the rising part of the laser pulse. The acceleration process continues for 3 ns , and, at a time of 10 ns , the shell enters into the

Fig. 6 (A) Temporal profile of laser pulse: dependence of the laser power on time, including the pre-pulse (1, $t < 4 \text{ ns}$), rising part (2) and full power (3, $t > 8 \text{ ns}$). (B) The shell implosion diagram: dependence of the radial position of the shell on time. Dashed blue line shows the first shock trajectory.

implosion phase. Its radius at this moment is ~ 0.5 mm and it is already compressed in the shocks. The acceleration is delayed by 3 ns with respect to the rising part of laser pulse, which is explained by the delay of energy transport between the absorption zone and the ablation layer, where the shock is formed.

The implosion phase takes a time of ~ 2 ns, and it ends with stagnation, which occurs at $t_3 \approx 12$ ns. At the beginning of the phase of implosion, the mass of the shell is 0.3 mg, its velocity is 240 km s^{-1} , and its kinetic energy is 8.6 kJ. Thus, the hydrodynamic efficiency of the acceleration of the shell is less than 9%.

A more detailed understanding of the evolution of the shell can be obtained by considering the trajectories of the first and second shocks in the mass coordinates shown in Fig. 7A. The bright line in the bottom left corner shows the trajectory of the first shock arriving at the inner edge of the shell at 7.3 ns and reflected back as a rarefaction wave (dark line). The line starting in the top left corner shows the ablation front that slowly moves downwards. The rarefaction wave is reflected at the time 8 ns from the ablation front, and this moment is synchronized with the arrival of the second shock. It propagates much faster than the first shock and arrives at the inner edge of the shell at 9 ns. After the launch of the second shock the shell is accelerated almost isentropically.

The details of the stagnation phase are presented in Fig. 7B. The shell density achieves its maximum value of 500 g cm^{-3} at 12.15 ns and then it decreases because of the expansion of the hot spot under the increasing pressure produced by fusion reactions. The hot spot radius at the maximum compression time is $28 \mu\text{m}$, its temperature is 10 keV and its density $\sim 35 \text{ g cm}^{-3}$. The areal density of $\sim 0.15 \text{ g cm}^{-2}$ in that case is sufficient for ignition. The areal density of the fuel is about 1 g cm^{-2} . This is a relatively low value, so the produced fusion energy of 19.5 MJ corresponds to a burn fraction of less than 10% of the initial target mass. The combustion time is extremely short in this example, the fusion energy yield increases in 20 ps from almost zero to its maximum value.

Hydrodynamic stability of the implosion process

This section presents the effects that may degrade the performance of the ICF target. They are related to a deviation of the shell from the ideal case of perfect spherical symmetry assumed in the previous sections. Any deviation from the spherical geometry compromises the conversion of the shell kinetic energy into the internal energy of compressed fuel and heating of the hot spot. The ablation pressure and the distribution of laser intensity over the target surface must be as uniform as possible. Hydrodynamic stability of the imploding shell is a subject of prime importance for ICF, it is discussed in detail in reviews and textbooks by Brueckner and Jorna (1974), Atzeni and Meyer-ter Vehn (2004), Lindl et al. (2004) and Craxton et al. (2015).

A perturbation of the target surface can be developed in a series of spherical functions characterized by the polar number, $l \geq 0$, and azimuthal number, $|m| \leq l$. Consequently, the distribution of the laser intensity over the target surface and shell density perturbations are characterized by the amplitudes of corresponding spherical harmonics.

Deviations from spherical symmetry are divided in two groups depending on their origin. Large scale perturbations with characteristic length larger than the shell initial thickness, corresponding to $l \leq 20$ –30, are due to target misplacement and asymmetry of laser irradiation. The small-scale perturbations with wavelengths of the order of the shell in-flight thickness, or smaller, depend strongly on the quality of the target surface and the smoothness of the laser beams. The initial perturbations are amplified during the implosion process for two reasons. Firstly, the relative amplitude of a perturbation, $\delta R/R$, increases because the shell radius decreases. The initial perturbation is thus multiplied by the convergence ratio at stagnation. Secondly, the amplitude of an initial perturbation increases with time because of hydrodynamic instabilities.

Two instabilities are of prime importance for ICF, the Rayleigh-Taylor and Richtmyer-Meshkov instabilities. The former operates during the shell acceleration and deceleration phases, while the latter is excited when the shock front crosses a modulated interface between two materials of different density. These hydrodynamic instabilities are identified as the major threat for the shell

Fig. 7 (A) Trajectories of the first (1) and second (2) shocks in the mass coordinates in the time interval from 6 to 11 ns. The first shock arrives at the inner edge of the shell at $t = 7.3$ ns. The white line (3) at the top shows the position of the shell outer edge. (B) Density profiles in the target during the stagnation showing the hot spot ($r < 30 \mu\text{m}$) and the compressed shell ($r \approx 30$ – $50 \mu\text{m}$).

implosion for two reasons. Firstly, the shell can be destroyed if its radial displacement becomes larger than the in-flight thickness. Having in mind that half of the shell is ablated and that the remaining part is compressed by at least a factor of 2–3, the typical value of the in-flight aspect ratio is $\mathcal{A}_{if} \sim 20$. This corresponds to a shell thickness of less than 5 μm at stagnation and imposes a severe constraint on the acceptable initial perturbation amplitude. Secondly, development of the instability during the deceleration phase leads to mixing of cold shell material with the gas in the hot spot. This effectively decreases the hot spot areal density and temperature, and penalizes ignition. The effect of the hot spot contraction because of shell deformation and fuel mixing is described empirically in one-dimensional simulations with a factor “yield over clean” (YOC), which is defined as a ratio of the measured neutron yield (in multidimensional simulations or in experiments) to that predicted in the corresponding one-dimensional simulation assuming ideal spherical symmetry.

Symmetry of implosion

The low modes are controlled by the focusing conditions and intensity profiles of the laser beams. The requirements on the symmetry of illumination depends on the shell compression. For a given convergence ratio C_R , the perturbation of the initial shell radius, δR_0 , is proportional to the perturbation of the implosion velocity, $\delta R_0/R_c = C_R \delta U_{\text{imp}}/U_{\text{imp}}$. The perturbation of the hot spot that can be tolerated at ignition is a fraction of the hot spot radius. Setting $\delta R_0/R_c \leq 0.2$, the condition on the implosion velocity is $\delta U_{\text{imp}}/U_{\text{imp}} \leq 0.2/C_R$. According to Eq. (16), the implosion velocity is proportional to the mass ablation rate, which depends on the laser intensity as $I_{\text{las}}^{1/3}$. Consequently, the constraint on the uniformity of laser irradiation is $\delta I_{\text{las}}/I_{\text{las}} \leq 0.6/C_R$. For realistic values of $C_R \sim 20\text{--}30$, the uniformity should be better than 1–2%.

Homogeneity of irradiation depends on the number of laser beams and their radial shape. Fig. 8 shows an example of optimization of the target irradiation performed by Hallo et al. (2009) in the framework of the project HiPER (Edwards and Danson, 2015). The facility is planned to have 48 laser beams distributed over a spherical chamber in three cones from each side of the chamber at angles 21.23 degrees (4 beams), 47.03 degrees (8 beams) and 74.96 degrees (12 beams) with respect to the North-South axis. The beam intensity profile

$$I_{\text{las}}(r) = I_0 \exp[-(r/R_{\text{las}})^{2m}] \quad (34)$$

is characterized by two dimensionless parameters, $a = R_{\text{las}}/R_0$ and m , defining the ratio of the beam radius to the target radius and steepness of the intensity profile, respectively. These parameters provide a flexibility for controlling the irradiation symmetry, which is characterized by a standard deviation

$$\sigma_{\text{rms}} = \left[\int (I - \langle I \rangle)^2 d\Omega \right]^{1/2} / \langle I \rangle \quad (35)$$

where the integral is performed over the target surface and $\langle I \rangle$ is the average intensity. The red point in the figure shows the optimal choice with $a \approx 0.6$ and $m \approx 1.0$, which gives homogeneity of irradiation of 0.15% with 94% of laser energy incident on target. It withstands an energy imbalance of 10% and beam pointing imbalance of 5% without compromising the target performance. The amplitude of the most dangerous mode, $l = 12$, defined by the geometry of beam distribution over the chamber, is 0.5% in this case.

Laser imprint

The perturbations at small scale, the high modes of the spherical functions, are dangerous because they can be unstable and grow significantly during the implosion. There are two sources of these perturbations: roughness of the target—small variations of the shell thickness, typically of a few nanometers, and the laser imprint—small perturbations of the laser beam intensity that produce

Fig. 8 Homogeneity of target irradiation σ_{rms} (35) in percent as a function of the laser beam radius $a = R_{\text{las}}/R_0$ and profile steepness m by using 48 laser beams with a super-Gaussian intensity profile calculated within the HiPER project (Edwards and Danson, 2015). Red point shows the optimized configuration with $\sigma_{\text{rms}} = 0.15\%$ and 94% of laser energy incident on target.

perturbations of the ablation pressure during the launch of the first shock. The latter is considered as a major issue for the direct drive approach.

A typical nanosecond laser pulse carries energy of a few kilojoules and contains several resonator modes. While focused on target, the mode interference produces a complicated intensity modulation with an amplitude incompatible with requirements on the homogeneity of ablation pressure. Several optical techniques have been developed for improving the laser intensity distribution, commonly called “laser beam smoothing”. They include spatial smoothing using phase plates, polarization smoothing by overlapping two spatially incoherent beams with perpendicular polarizations and temporal smoothing with laser beam spectral broadening.

Spatial smoothing is the method that involves splitting the laser beam entering into the interaction chamber into many (from a few hundred to a few thousand) spatially incoherent beamlets with a random phase plate (RPP) as proposed by [Kato and Mima \(1982\)](#). This allows conversion of an uncontrolled beam interference pattern into an ensemble of small-scale speckles with a transverse scale of about 10 laser wavelengths and homogeneously distributed over the laser focal spot. The speckle statistics follows an exponential distribution and is rather reproducible. A combination of two laser beams with orthogonal polarizations allows a doubling of the number of speckles while maintaining the same average intensity, thus reducing the amplitude of intensity fluctuations on the target.

While spatial laser beam smoothing significantly improved the quality of laser plasma interaction since it was introduced in the 1990s, see [Lindl et al. \(2004\)](#) and [Craxton et al. \(2015\)](#), it is not sufficient for reducing the laser imprint. Temporal smoothing aims at reducing the speckle lifetime to a few tens of picoseconds, thus reducing significantly the time averaged amplitude of intensity modulations. This is achieved by the method of smoothing by spectral dispersion (SSD)—a phase modulation of the laser beam across its transverse profile, as proposed by [Skupsky et al. \(1989\)](#). For a typical frequency of the electro-optical modulator of 17 GHz and depth of modulation of 5, the effective speckle lifetime can be decreased to about 12 ps. Larger spectral widths are incompatible with the existing technique of frequency conversion of the Nd:glass laser, operating on a wavelength of $\sim 1 \mu\text{m}$, into the third harmonic used in the ICF research.

Modulations of laser intensity in the absorption zone can be related to the modulations of the ablation pressure by using Eq. (3), but one should also account for the smoothing effect due to the heat transport in the conduction zone. As suggested by [Bodner \(1981\)](#), this can be described by a “cloudy day” model, namely, due to the lateral electron heat transport the amplitude of intensity modulations in the conduction zone decreases by a factor $\exp(-kd_c)$, where k is perturbation wave number and d_c is the thickness of the conduction zone. Thus, one can evaluate the amplitude of ablation pressure modulations as

$$\delta p_{\text{abl}}/p_{\text{abl}} \approx (2/3) \exp(-kd_c) \delta I_{\text{las}}/I_{\text{las}} \quad (36)$$

As the thickness of the conduction zone increases with time because of plasma expansion, the most dangerous laser imprint is produced at the beginning of the laser pulse, during the first nanosecond, when the ablation surface is very close to the critical surface. Unfortunately, temporal smoothing does not sufficiently improve the situation, because the intensity modulation pattern is established during the first modulation period, which is, in practice, approximately a few tenths of a nanosecond, comparable with the plasma expansion time.

Several methods have been developed for imprint mitigation, all of them attempting to increase the thickness of the conduction zone before the laser pulse arrival. They include: the use of an X-ray flash or low intensity laser pulse to ionize the external layer of the shell, covering the shell with a low density foam layer which can be ionized by X-rays or a laser pre-pulse, or by adding mid-Z elements as dopants in the ablator in order to increase the contribution of radiation transport. These techniques, which are of prime importance for direct drive ICF, are described by [Craxton et al. \(2015\)](#).

Rayleigh-Taylor instability

The hydrodynamic Rayleigh-Taylor (RT) instability develops at the interface of two fluids of different densities under a gravitational force or an acceleration. In the ICF context, this configuration occurs either during the shell acceleration by the ablation pressure acting on the outer shell interface, or during the shell deceleration on the inner shell interface under the pressure of the compressed hot spot. A particular case of the RT instability is the Richtmyer-Meshkov (RM) instability, occurring at a perturbed interface crossed by a planar shock. In all cases the perturbation amplitude is proportional to the initial perturbation and depends on the perturbation wavelength, $2\pi/k$, in the interface plane. The particularity of these instabilities in the ICF context is the mass flow across the interface due to ablation, which plays an important stabilizing role.

The basic mechanism of this instability can be understood by considering an interface between two liquids, a heavy one with a mass density, ρ_1 , and a light one with a mass density, ρ_2 , in a gravitational field with acceleration g directed along the vertical axis z . This configuration is stable if the interface is plane and perpendicular to the z axis, as the gravitational forces $\rho_{1,2}gz$ are perpendicular to the interface and the liquids can be considered as incompressible.

However, the stability is lost if the interface $z = 0$ is perturbed, $\xi(x) = \xi_0(t) \sin kx$. Then, there is an uncompensated tangential component of the force producing acceleration of fluids parallel to the interface according to the Euler equation:

$$\rho_{1,2} dv_{x1,2}/dt = \rho_{1,2} kg \xi \quad (37)$$

where the factor $k\xi$ accounts for the component of the gravitational force acting along the surface. As the fluids are incompressible, the tangential components of the velocities have opposite signs, $v_{x1} = -v_{x2} = v_x$, while the normal components are equal,

$v_{z1} = v_{z2} = v_z = d\xi/dt$. Moreover, incompressibility implies that $v_x \approx v_z$. Consequently, subtracting Eqs. (37) at both sides of the interface, we have:

$$(\rho_1 + \rho_2)d^2\xi/dt^2 = (\rho_1 - \rho_2)kg\xi \quad (38)$$

This equation describes gravitational waves with frequency, $\omega = \sqrt{|A_t|kg}$, if the Attwood number, $A_t = (\rho_1 - \rho_2)/(\rho_1 + \rho_2)$, is negative, that is, the light fluid is above the heavy one. In contrast, it corresponds to an instability growing exponentially, $\xi_0(t) \propto \exp(\gamma t)$, with the growth rate, $\gamma = \sqrt{A_t kg}$, if the heavy fluid is above the light one, $\rho_1 > \rho_2$.

The Richtmyer-Meshkov instability is a special case where a modulated interface is accelerated for a short time at the shock wave front. Then Eq. (38) can be written as $dv_x/dt = A_t kg\xi$, and, integrating this equation, we obtain that there is a modulation of the flow velocity behind the shock: $\delta v_z \approx A_t k D_s \xi_0$, where D_s is the shock front velocity. Consequently, the interface perturbation grows linearly with time:

$$\xi_0(t) = \xi_0(0)(1 + A_t k D_s t) \quad (39)$$

This expression applies, for example, to the interface between ablator and fuel, where perturbations can grow with time downstream of the first shock and will be further amplified exponentially by the RT instability during the acceleration phase. Both instabilities are strongly modified at the ablation surface.

Hydrodynamic instabilities at the ablation front

The presence of the conduction zone in close contact with the ablation surface strongly modifies the hydrodynamic instabilities. Firstly, the density of the blowoff plasma is much smaller than the solid density, so the Attwood number is close to 1 and thus the second equation in (37) can be neglected. Secondly, the conduction layer has a finite thickness, d_c , typically of a few microns, and perturbations with shorter wavelengths, $kd_c > 1$, are suppressed due to the efficient lateral electron heat conduction, similarly to the “cloudy day” model (36).

Moreover, for the long wavelength modes, $kd_c \ll 1$, there are two stabilizing factors related to the mass flow across the ablation front and the electron heat flux. Firstly, the fluid element remains in the unstable zone only a finite time, which can be estimated as the ratio of the thickness of the perturbed layer, $1/k$, to the flow velocity, D_a . Consequently, the RT growth rate is reduced by a factor kD_a , where $D_a = \dot{m}_a/\rho_1$ is the ablation velocity (3).

Secondly, the ablated plasma is a compressible fluid, and modulations of the ablation front result in a variation of the thickness of the conduction zone. Namely, a protrusion of the ablation front into a hot blowoff plasma makes the conduction zone thinner and, correspondingly, results in a higher temperature gradient, a higher heat flux and a higher ablation rate. This is called the “fire polishing” effect. This effect results also in an increase of ablation pressure, which acts in the direction opposite to the acceleration and, therefore, reduces the instability growth rate. The force related to this overpressure effect can be estimated as a projection of the pressure gradient, $k p_{abl}$, on the direction normal to the perturbed ablation front, thus resulting in the restoring force $\sim k^2 p_{abl} \xi$.

These two stabilizing effects bring two additional terms in Eq. (38) describing the temporal evolution of the perturbation of the ablation surface. It takes the following form:

$$\rho_1 d^2\xi/dt^2 + k\rho_1 D_a d\xi/dt = \rho_1 kg\xi - k^2 p_{abl} \xi \quad (40)$$

The second term on the left hand side accounts for the mass flow. It is similar to the corresponding term in the rocket model, section “Shell acceleration by ablation pressure”. The second term on the right hand side corresponds to the overpressure effect. While the complete theoretical expression for the RT growth rate is quite complicated, it turns out that it can be interpolated by a simple empirical formula proposed by Takabe et al. (1983):

$$\gamma \approx \alpha \sqrt{kg/(1 + kd_c)} - \beta k D_a \quad (41)$$

where $\alpha \approx 0.9$ and $\beta \approx 3.1$ are two adjustable parameters, dependent on the shell material. The term under the square root describes the effect of suppression of short wavelength modes due to the finite thickness of the conduction layer, and the second term in the right hand side is related to the mass flow. A remarkable feature of this formula is the stabilizing role of the ablation for long wavelength perturbations and the prediction of a cutoff wave number. Typically, in Omega and NIF implosion experiments, the RT instability cutoff corresponds to the spherical mode number $l \approx 100$ –200.

The stabilizing effects related to ablation are very important for the ICF target design. They suggest a spatial shaping of the ablator density and entropy in such a way that the external part of the shell has a lower density and high temperature, while the internal part of the shell, including fuel, remains cold and does not compromise the implosion. This shaping of the ablator entropy is achieved with a short laser prepulse which heats and compresses the external part of the shell, thus stabilizing the ablation front. This technique of adiabat shaping has been developed and implemented at the Omega laser facility in the context of direct drive implosions, see Craxton et al. (2015).

The exponential growth of the ablation front perturbation corresponds to the linear stage of the RT instability development; it is limited to a perturbation amplitude smaller than 10% of the wavelength. For longer times and larger amplitudes, the instability enters into a nonlinear phase with a slower growth of the perturbation amplitude followed by mixing of the cold material with the hot blowoff plasma. This is a highly undesirable effect for ICF and has to be avoided.

The proximity of the conduction zone also has a notable effect on the Richtmyer-Meshkov instability. After the shock crosses the ablation surface, the latter is accelerated to the velocity, $\delta v_z \approx k D_s \xi_0$, but its further evolution is affected by the overpressure effect. The restoring force in the right hand side of Eq. (40) stops the linear growth of the initial perturbation and results in oscillations of the ablation surface with a frequency $\omega_{RM} \approx k \sqrt{D_a v_{bf}}$. The amplitude of oscillations is related to the initial shock perturbation as $\delta v_z / \omega_{RM} \approx \xi_0 D_s / \sqrt{D_a v_{bf}}$. These oscillations evolve during the time the first shock crosses the shell. They produce a seed for development of the RT instability when the shell is accelerated as a whole. Furthermore, the oscillations of the ablation surface penetrate inside the shell and produce feedthrough perturbations at the inner shell surface where the RT instability develops at the deceleration stage. The most dangerous perturbations are those having a wavelength on the order of the shell thickness, corresponding to the spherical mode number $l \sim \mathcal{A}_{if}$. They grow more rapidly than lower modes and efficiently penetrate through the shell. This fact explains the fragility of very thin shells and is one of the major limiting factors of target compression.

Laser plasma interactions in the ICF context

Laser radiation is the best suited for driving inertial fusion targets. It is a unique source capable of providing extreme powers, on the level of a few hundred terawatts, needed to bring the DT fuel to ignition conditions. However, the physics of laser plasma interactions is complicated and is a source of several serious issues. Firstly, the electromagnetic temporal and spatial scales of a few femtoseconds and a few microns are incompatible with the ICF scales of hundreds of picoseconds and hundreds of microns. So, the physics of laser plasma interactions is considered separately and introduced in the global ICF model in a simplified fashion. Secondly, laser radiation in the optical domain cannot reach the dense plasma, it is absorbed or reflected, at the critical density, which is 10–100 times smaller than the solid density. Therefore, one should ensure an efficient laser energy absorption in such a low density plasma and efficient energy transport from the absorption zone to the solid densities. Thirdly, the laser intensities needed for target implosion are rather high, at the level of 10^{14} – 10^{15} W cm⁻², so that the electron quiver velocity in the laser field is comparable to (but smaller than) the electron thermal velocity, so the laser plasma interaction becomes nonlinear, resulting in excitation of parametric instabilities. This leads to modification of the laser propagation, enhanced scattering and the generation of suprathermal (hot) electrons, which are undesirable for ICF.

These three major issues for ICF are discussed in this section. A more detailed description of laser plasma interactions in the ICF context can be found in reviews and textbooks by [Kruer \(2003\)](#); [Atzeni and Meyer-ter Vehn \(2004\)](#); [Lindl et al. \(2004\)](#) and [Craxton et al. \(2015\)](#).

Laser propagation in an inhomogeneous plasma

Laser radiation is quasi-monochromatic and the laser period is much shorter than characteristic hydrodynamic scales. Thus it can be described by Maxwell's equations in the envelope approximation with the electric field written as $\text{Re} E \exp(-i\omega_{las}t)$, with the complex amplitude, E , slowly varying over the laser period, $2\pi/\omega_{las}$, and wavelength, λ_{las} . The magnetic field is then defined by the Faraday's and Ampere's equations:

$$\mathbf{B} = -(i/\omega_{las}) \text{rot} \mathbf{E}, \quad \text{rot} \mathbf{B} = -i(\omega_{las}/c^2) \varepsilon(\omega_{las}) \mathbf{E} \quad (42)$$

Here $\varepsilon(\omega_{las})$ is the plasma dielectric permittivity, which has a simple form, $\varepsilon = 1 - \omega_{pe}^2/\omega_{las}^2$, where $\omega_{pe} = (e^2 n_e / m_e \varepsilon_0)^{1/2}$ is the electron plasma frequency, ε_0 is the vacuum permittivity and the ion contribution is neglected because of a large ion-to-electron mass ratio.

In the geometrical optics approximation, $\mathbf{E} \propto \exp(i \int \mathbf{k}_{las} \cdot d\mathbf{r})$, from these two equations one obtains a dispersion equation,

$$k_{las}^2 c^2 / \omega_{las}^2 - \varepsilon = 0 \quad (43)$$

As the first term in the left hand side is positive, the laser may propagate only in a transparent plasma where $\varepsilon > 0$. As the laser propagates in a plasma with increasing density, the dielectric permittivity and the wave number decrease and they are equal to zero at the critical density, $n_{cr} = m_e \varepsilon_0 \omega_{las}^2 / e^2$. Thus, the laser cannot propagate deeper into plasma and is reflected. The plasma critical density can be represented as $n_{cr} = 1.1 \times 10^{21} \lambda_{las}^{-2}$ cm⁻³, where the laser wavelength λ_{las} is in microns. In fact, this density is accessible only at normal laser incidence, otherwise the laser radiation is reflected at lower densities.

The expression on the left hand side of Eq. (43) can be considered as the Hamiltonian of a classical particle of unit mass and with a dimensionless momentum, $\mathbf{k}_{las} c / \omega_{las}$, moving in a potential of $\frac{1}{2} \varepsilon(\mathbf{r})$. Consequently, the trajectory of an optical ray can be found from the principle of minimum action

$$d\mathbf{r}/ds = \mathbf{k}_{las} c / \omega_{las}, \quad d\mathbf{k}_{las}/ds = (\omega_{las}/2c) \nabla \varepsilon \quad (44)$$

where s is an effective time, which, in this case, is a coordinate along the ray. According to these equations, the trajectory of a laser ray incident obliquely on a plasma with a linear density profile, $\varepsilon = 1 - z/L_n$, is a parabola, similar to the particle trajectory in a constant gravitational field. For the angle of incidence θ , the perpendicular component of the wave vector is conserved, $k_{las \perp} = (\omega_{las}/c) \sin \theta$, while the parallel component decreases to zero at the turning point, $z_t = L_n \cos^2 \theta$.

The equations of geometrical optics (44) constitute the basis for modeling of laser propagation in ICF hydrodynamics. Namely, the laser beams incident on a plasma are split into many rays, each of them carrying a fraction of the total beam power and propagating along its own trajectory defined by the electron density profile provided by solution of the hydrodynamic equations. As the light velocity is much larger than the plasma fluid velocity, the ray propagation is considered to be instantaneous. The laser energy deposition in the plasma is calculated at each time step as a sum of the energy deposition of each ray along its trajectory according to the imaginary part of the dielectric permittivity:

$$dP/ds = -\kappa_{IB}P \quad (45)$$

where P is the ray power and $\kappa_{IB} = (\omega_{las}/c) \text{Im}\epsilon (\text{Re}\epsilon)^{-1/2}$ is the absorption coefficient. In the ICF-relevant conditions, it is defined by electron-ion collisions, $\kappa_{IB} = (\nu_{ei}/c)(n_e/n_{cr})(1 - n_e/n_{cr})^{-1/2}$, where

$$\nu_{ei} = \frac{Ze^4 n_e \ln\Lambda}{3\epsilon_0^2 m_e (2\pi T_e)^{3/2}}$$

is the electron-ion collision frequency and $\ln\Lambda$ is the Coulomb logarithm. This is the inverse bremsstrahlung process.

In an inhomogeneous plasma, the collisional absorption rate, κ_{IB} , increases as the square of the plasma density, so the maximum of absorbed energy is localized near the critical density. In particular, in the case of a linear density profile, $n_e(z) = n_{cr}z/L_n$, Eq. (45) can be integrated explicitly providing the following expression for the absorption coefficient

$$\eta_{abs} = 1 - \exp\left(-\frac{32}{15}\tau_{IB}\cos^5\theta\right) \quad (46)$$

where $\tau_{IB} = \nu_{ei,cr}L_n/c$ is the plasma optical thickness, and $\nu_{ei,cr}$ is the collision frequency at the critical density. The value of τ_{IB} defines the efficiency of collisional absorption. Its dependence on the ion charge and density favors short laser wavelengths and high ion charge. At the wavelength of $0.35\text{ }\mu\text{m}$ and at normal incidence, the absorption coefficient increases from 60% for a DT plasma to 70% for a CH plasma. An efficient laser collisional absorption is one of motivations for converting Nd laser radiation generated at $1\text{ }\mu\text{m}$ wavelength to the second and third harmonics.

Laser collisional absorption depends strongly on the angle of incidence. According to Eq. (46), absorption is reduced by a factor of 2 for a ray incidence angle of $\theta = 30$ degrees with respect to the density gradient. Oblique incidence is inevitable in ICF-relevant conditions, where the laser beam width is comparable to the target size. Moreover, the laser beams arriving from different directions on the target cross over in plasma, thus creating a complicated intensity pattern. Fig. 9 shows an example of two laser beams incident on a spherical target.

The geometrical optics model provides, however, a very basic description of the laser plasma interaction, limiting it simply to collisional (inverse bremsstrahlung) absorption. Each ray propagates independently and interference effects are not accounted for. Moreover, each ray carries a power, but the intensity of laser radiation within the plasma is not known. Therefore, nonlinear and polarization effects are out of scope of this model. This is not adequate for ICF conditions, where effects such as resonance absorption, cross beam energy transfer, excitation of parametric instabilities have to be considered. These effects are discussed in the next sections.

Fig. 9 Example of ray trajectories of two laser beams incident at angles ± 30 degrees on a spherical target with electron density increasing linearly from 0 to $1.2n_{cr}$ between the two white circles.

Resonance absorption

In the case of oblique incidence on a plasma of the laser wave polarized in the plane of incidence there is another mechanism of absorption related to a resonance excitation of plasma waves with frequency equal to the laser frequency. Because of the resonance condition, $\omega_{\text{las}} = \omega_{pe}$, this process takes place near the critical density. However, the absorbed energy does not go to plasma heating, but to acceleration of a relatively small group of resonant electrons to high energies.

Let us consider a plane laser wave with amplitude, E_0 , incident at angle, θ , in the y, z plane on a plasma with a linear density profile, $n_e = n_{cz}/L_n$. The resonant absorption occurs for the wave having the electric field in the plane of incidence, y, z . This wave is reflected at the point, $z_r = L_n \cos^2 \theta$, but the evanescent field component, E_z , parallel to the gradient penetrates to the critical point, $z_r = L_n$, and excites there an electron plasma wave. Solution of the Maxwell's equations for a linear density profile in the case $\omega_{\text{las}} L_n / c \gg 1$ provides the following expression for the driver field, see [Kruer \(2003\)](#):

$$E_z(z_{cr}) = E_{\text{las}} (2\pi\omega_{\text{las}} L_n / c)^{-1/2} \phi(q) \quad (47)$$

where $q = (\omega_{\text{las}} L_n / c)^{1/3} \sin \theta$ and ϕ is the resonance function, $\phi(q) \approx q \exp(-2q/3)$. It is zero for the case of normal incidence and increases with θ , achieving a maximum for an optimal angle $\theta_{\text{res}} \approx 0.7 (\omega_{\text{las}} L_n / c)^{-1/3}$, then decreases exponentially.

The function ϕ characterizes the laser absorption, that is, the efficiency of conversion of the incident laser energy flux into the energy of plasma waves: $\eta_{\text{res}} \approx \frac{1}{2} \phi^2(q)$. The maximum value of the resonance absorption coefficient is approximately 50%, but it is limited to relatively small angles of incidence. The energy transferred to the plasma waves is eventually absorbed in plasma. Depending on the plasma temperature two absorption mechanisms are possible. In a low temperature plasma, if the characteristic collision frequency is sufficiently large, $\nu_{ei,cr} / \omega_{\text{las}} \gg (\lambda_D / L_n)^{2/3}$, where λ_D is the electron Debye length, the width of the resonance is determined by collisions, $\Delta z_{\text{res}} \approx L_n \nu_{ei,cr} / \omega_{\text{las}}$, and the electron distribution remains approximately Maxwellian. In the opposite case, corresponding to ICF conditions, Landau damping is dominant and the absorbed energy is transferred to the resonant electrons. The characteristic width of the plasma resonance in that case, $\Delta z_{\text{res}} \approx (\lambda_D^2 L_n)^{1/3}$, corresponds to the phase velocity of the plasma wave, $v_{ph} \approx \omega_{pe} \Delta z_{\text{res}}$. Thus, the characteristic energy of accelerated electrons is a factor of $(L_n / \lambda_D)^{2/3}$ higher than the temperature of cold electrons, T_c , at the critical density. The energy flux of these electrons is directed into the lower density plasma, opposite to the density gradient, but the accelerated electrons are returned by the self-consistent electric field and penetrate into the overdense plasma behind the ablation front. They may preheat fuel and compromise compression.

This linear model of resonance absorption applies to relatively low laser intensities, when the ponderomotive pressure of resonantly excited plasma waves is smaller than the plasma thermal pressure. At intensities exceeding $10^{14} \text{ W cm}^{-2}$, the resonantly excited plasma wave produces a steepening of the density profile, so that the characteristic density scale length decreases and becomes comparable to the laser vacuum wavelength. Analytic estimates and numerical simulations conducted by [Estabrook et al. \(1975\)](#) and [Forslund et al. \(1977\)](#) have led to the following conclusions concerning the nonlinear resonance absorption: (i) plasma density profile steepening leads to increase of the absorption efficiency and optimal angle of incidence; (ii) the energy of hot electrons produced due to the resonance absorption significantly decreases; (iii) parametric instabilities that may be excited near the critical density are suppressed. The energy distribution of accelerated electrons has approximately an exponential form and can be characterized by a hot electron temperature, see [Forslund et al. \(1977\)](#):

$$T_h \approx 30 (I_{\text{las}} \lambda_{\text{las}}^2)^{1/3} T_c^{1/3} \text{ keV} \quad (48)$$

where T_c is the temperature of bulk electrons in keV, the laser intensity at the turning point is in units of $10^{15} \text{ W cm}^{-2}$ and the laser wavelength in microns. A combination of $I_{\text{las}} \lambda_{\text{las}}^2$ is proportional to the quiver energy of electron in the laser field; this is the main parameter characterizing nonlinear laser plasma interaction processes.

Resonance absorption was considered as an important process in the early years of ICF, when long wavelength lasers at 10 and 1 μm were used in experiments. Transition to short wavelengths, 0.5 and 0.35 μm , has significantly diminished the role of the resonance absorption for two reasons: firstly, the collisional absorption is more efficient, significantly decreasing the laser intensity near the critical density and, consequently, the fraction of laser energy transferred to resonant electrons to a few percent; secondly, the laser irradiance, $I_{\text{las}} \lambda_{\text{las}}^2$, decreases at shorter wavelengths, so the hot electron temperature (48) typically does not exceed 20–30 keV and does not present a notable risk of fuel preheat.

Parametric instabilities

When the laser irradiance, $I_{\text{las}} \lambda_{\text{las}}^2$, exceeds a few times $10^{14} \text{ W } \mu\text{m}^2 \text{ cm}^{-2}$, the temperature of the plasma corona increases above 1 keV, collisional absorption rapidly decreases and the laser plasma interaction is dominated by the nonlinear effects. The most important under ICF-relevant conditions are the following nonlinear processes: laser beam self-focusing and filamentation, and parametric instabilities: stimulated Raman and Brillouin scattering (SRS and SBS) and two plasmon decay (TPD). All these processes take place in the laser propagation zone, to the right of the critical surface in [Fig. 2](#). The domain of operation of parametric processes is shown in more detail in [Fig. 10](#).

Filamentation and SBS (stimulated scattering on low frequency ion acoustic waves) may develop at all densities in the range $n_e < n_{cr}$; they are responsible for laser intensity modulation and reflection of laser light before it accesses the zone of efficient absorption. TPD develops in a narrow zone of plasma with a density close to one quarter of the critical density. It corresponds to a resonant

Fig. 10 Domains of operation of different parametric processes in terms of the plasma density profile, $n_e(r)$. Laser radiation comes from the right. Green and red marks show the positions of the resonance absorption near the critical density, n_{cr} , and two plasmon decay near one quarter of the critical density, $\frac{1}{4}n_{cr}$.

excitation of plasma waves with frequency equal approximately to one half of the laser frequency. These waves typically have a phase velocity much larger than the electron thermal velocity and thus may accelerate electrons to high energies. TPD excitation is manifested by the appearance in the spectrum of reflected light fractional harmonics with the frequencies $\frac{1}{2}\omega_{las}$, $\frac{3}{2}\omega_{las}$ and $\frac{5}{2}\omega_{las}$, which are produced due to scattering of the incident and reflected laser waves on the TPD-driven plasma waves. SRS, stimulated scattering on electron plasma waves, develops in plasmas with densities smaller than one quarter of the critical density. It transfers a part of laser energy to plasma waves, and consequently to energetic electrons, and another part to scattered electromagnetic waves. The ratio between these two components, according to the Manley-Rowe relation, is proportional to the ratio of the frequencies of the corresponding waves, $\omega_{pe}/(\omega_{las} - \omega_{pe})$. So, up to a half of the incident laser energy can be transferred to plasma waves.

Often these parametric processes are considered as undesirable because they reflect a significant portion of the laser light (SBS and SRS), modulate the laser beam intensity thus creating high intensity spots (filamentation), redistribute the laser energy over the absorption zone due to the cross-talk between the overlapping beams arriving from different directions (cross beam energy transfer, CBET), and generate large amounts of energetic electrons due to excitation of large amplitude plasma waves (TPD and SRS).

While parametric processes have been studied experimentally and theoretically for more than 50 years, understanding of their role in the ICF context is still far from being complete. This is explained first of all by the fact that plasma instabilities develop on a microscopic scale, which cannot be resolved in hydrodynamic simulations and in integrated experiments. There is a disparity, therefore, between the detailed local microscopic models and kinetic simulations and their implementation in the ICF hydrodynamic codes. The major obstacle is related to the geometrical optics model describing laser energy deposition in the plasma, which does not account for the interference pattern of laser beams and does not provide access to the local values of laser intensity in the plasma, which is indispensable for characterization of nonlinear effects. Another issue is related to suprathermal (hot) electrons, which have a large mean free path and their energy deposition in the plasma has to be described with special modules for nonlocal energy transport.

The role of parametric instabilities in scattering of laser energy and generation of hot electrons has been demonstrated in early ICF studies in the 1970s and 1980s by McCall (1983) and Lindl et al. (2004), and resulted in the complete reorientation of the ICF programs. Namely, the CO₂ gas lasers operating at a wavelength of 10.6 μm were abandoned, and Nd:glass lasers operating at a wavelength of 1.06 μm were converted into the third harmonic. Moreover, laser beam smoothing techniques have been introduced (see section “Laser imprint”), providing a much better control on the overall intensity distribution on the target. While these measures have certainly improved the quality of laser energy deposition and suppressed undesirable nonlinear processes, they did not completely eliminate them. Large scale integrated experiments conducted during the last decade on the Omega and NIF facilities have demonstrated significant energy losses due to SBS, SRS and CBET, and generation of large populations of hot electrons due to SRS and TPD, see Kirkwood et al. (2013) and Craxton et al. (2015). In what follows, we describe the role of parametric instabilities in the ICF context and methods for their modeling with hydrodynamic codes.

Laser beam filamentation

Self-focusing is an important process that can modify the propagation of a high power laser beam in a low density part of the plasma located in front of the absorption region. The technique of laser beam smoothing employed at high energy laser facilities includes random phase plates and smoothing by spectral dispersion. It allows suppression of the global laser beam self-focusing by splitting the whole beam into multiple mutually incoherent beamlets, each of them carrying a much smaller power. In the focusing plane these beamlets create an interference pattern that is called *speckles*. Each speckle can be considered locally as a Gaussian beam with a width, $w_s \sim \lambda_{las} F/D$, defined by the whole laser beam aperture, D , the focal distance, F , and length, $l_s = \pi w_s^2 / \lambda_{las}$, with the maximum intensity, I_s , following an exponential probability distribution, $p_s(I_s) \propto \exp(-I_s/\langle I \rangle)$, where $\langle I \rangle$ is the average laser intensity on target.

Self-focusing of each laser speckle takes place if the speckle power, $P_s = I_s \pi w_s^2$, exceeds the critical power for the ponderomotive self-focusing, $P_c = 1.86 v_g n_{cr} T_e / r_{cl} n_e$, where v_g is the group light velocity and r_{cl} is the classical electron radius. It can be written in a convenient form as

$$P_c = 32 T_e (n_{cr} / n_e) \sqrt{1 - n_e / n_{cr}} \text{ MW} \quad (49)$$

where the electron temperature is in keV. For the typical ICF conditions with a laser wavelength $0.35 \mu\text{m}$ and focusing optics $F/D \approx 8$, the speckle radius is $w_s \approx 2.5 \mu\text{m}$ and the average speckle power, $\langle P \rangle \approx 0.2 \text{ GW}$, is of the order of the critical power for the laser intensity, $I_{las} \sim 10^{15} \text{ W cm}^{-2}$. Thus, speckles with intensity above average may undergo self-focusing. This leads to a local increase of laser intensity in a speckle, a modification of the speckle probability distribution with an increase of the number of high intensity speckles, which become the site of secondary parametric instabilities.

The time of self-focusing development can be estimated as the time for ion acoustic wave propagation across the speckle, $t_s = w_s / c_s$. For the typical ion acoustic velocity, of the order of $0.3\text{--}0.4 \mu\text{m ps}^{-1}$, this time is about $5\text{--}10 \text{ ps}$. It is comparable to the laser pulse correlation time introduced by smoothing using spectral dispersion (SSD, see section “Laser imprint”). Thus, this temporal smoothing technique introduced by Skupsky et al. (1989) is an efficient tool for control and suppression of speckle self-focusing under ICF-relevant conditions.

Stimulated Brillouin scattering

Stimulated Brillouin scattering (SBS) corresponds to scattering of the incident laser light on an ion acoustic wave in the plasma. The scattered light may propagate in different directions, but SBS in the backward direction usually dominates, thus reducing the amount of laser light accessing the zone of absorption. SBS is a convective instability, that is, the scattered wave of a given frequency, ω_s , is amplified as it propagates in a spatially inhomogeneous plasma through the resonance region where the beat frequency, $\omega_{las} - \omega_s$, equals the ion acoustic frequency, $\omega_{iaw} = k v_s$. The resonance wave number k_{iaw} is defined by a zero detuning condition, $\Delta k(z) = 0$, where the wave number detuning for the backward scattering reads:

$$\Delta k(z) = k_{iaw}(\omega_{las} - \omega_s) - k_{las}(\omega_{las}) - k_s(\omega_s) \quad (50)$$

The width of the resonance, $\Delta z_{res} \approx (\Delta k')^{-1/2}$, is defined by the condition of small detuning, $\int_{\Delta z_{res}} |\Delta k| dz \sim 1$, where $\Delta k'$ is the spatial derivative of the wave numbers of three interacting waves in the resonance point, $\Delta k(z_{res}) = 0$. The gain factor of the scattered wave, $G = \ln(I_s/I_{s0})$, has been calculated by Rosenbluth (1972) in the WKB approximation, assuming that the width of the resonance region is larger than the wavelengths of the interacting waves:

$$G = \frac{2\pi\gamma_0^2}{|\Delta k' v_{g1} v_{g2}|} \quad (51)$$

where $v_{g1,2}$ are the group velocities of the ion acoustic and scattered waves at the resonance, $v_{g1} = v_s$ and $v_{g2} \approx k_{las} c^2 / \omega_{las}$. The SBS temporal growth rate in a homogeneous plasma, $\gamma_0 \approx 2^{-3/2} \omega_{pi} v_{las} (k_{las} / \omega_{las} v_s)^{1/2}$ is proportional to the electron quiver velocity in the laser field, $v_{las} = e E_{las} / m_e \omega_{las}$.

For SBS, the major factor limiting the width of the amplification region and gain is the inhomogeneity of the ion acoustic wave velocity, $v_s = c_s + u$, where $u(z)$ is the plasma expansion velocity. The phase detuning can be written as $\Delta k' \approx k_{iaw} / L_u$ where $L_u = c_s / (dv_s/dz)$ is the characteristic velocity scale length, and the expression for the SBS gain reads, see Liu et al. (1974):

$$G_{SBS} = \frac{\pi}{8} \frac{n_e}{n_{cr}} \frac{v_{las}^2}{v_{te}^2} \frac{\omega_{las}^2}{k_{las} c^2} L_u \quad (52)$$

The condition $G_{SBS} \gg 1$ corresponds to a strong amplification of the scattered wave from the thermal noise level. The characteristic time of SBS development, $\sim \gamma_0^{-1}$, is on the order of a picosecond. Similarly to self-focusing, it can be controlled by SSD or other methods of laser spectral broadening.

Cross beam energy transfer

SBS is considered as a moderately dangerous nonlinear process. The measured level of backward reflected light in the focusing optics rarely exceeds 10–15% in integrated ICF experiments, with approximately the same amount of light scattered at other angles. More attention was attracted recently to a special form of SBS in the zone of overlapping of two or more laser beams. This situation is common for any laser fusion scheme. In the direct drive approach, many beams are overlapping at the target surface with the goal of creating as homogeneous an irradiation field as possible (see section “Laser imprint” and Fig. 9). In indirect drive, many laser beams are overlapping in the laser entrance aperture of the hohlraum, producing a complicated interference pattern. These beams are interacting strongly in the sonic point where the local plasma expansion velocity is equal to the acoustic velocity, $c_s + u = 0$. As the plasma expands toward the laser, the incident wave is upshifted in the plasma reference system and it transfers its energy to the downshifted reflected wave. As both waves have comparable amplitudes, this process of cross beam energy transfer (CBET) is efficient even at modest gains, $G_{SBS} \sim 1$, and results in energy losses of up to 40%, see Myatt et al. (2014). The effect of speckle self-focusing on CBET has been considered by Raj and Hüller (2017).

Because of such a strong impact on the energy balance, methods for CBET numerical modeling and mitigation have been developed. In the indirect drive experiments on NIF, a frequency shift between the outer and inner laser beams was introduced. This

permitted compensation of the excessive energy losses of the inner beams due to Raman scattering and improved the implosion symmetry, see Michel et al. (2010). In direct drive experiments, in addition to the frequency shift between the laser beams, other CBET mitigation methods have been tested—reduction of laser beam width on the target and doping the ablator with high-Z elements. Unfortunately, none of these methods provided satisfactory results because of secondary effects: reduction of the laser beam waist degrades the low mode implosion symmetry (see section “Symmetry of implosion”), while doping of the ablator decreases the hydrodynamic efficiency (see section “Rocket model”).

Online numerical modeling of CBET with hydrodynamic codes requires knowledge of the laser intensity distribution in the plasma. Several methods of laser intensity evaluation have been developed. The ray-based method proposed by Igumenshchev et al. (2012) evaluates the distance between the adjacent ray trajectories and thus accounts for the laser beam intensity variation due to plasma refraction. The energy exchange between beams has been calculated by pair-wise coupling of all intersecting beams with the corresponding SBS gain. Although this method shows an improved agreement with experiment, it is numerically cumbersome and does not conserve the energy. Another method of “thick rays” considers each ray as an elementary Gaussian beam and solves an equation for the beam front curvature along the ray trajectory, see Colaitis et al. (2016). The pair-wise coupling in this approach is energy conserving and the calculations are less time consuming. However, spatial resolution of these methods is limited by the hydrodynamic mesh size and it cannot resolve the speckle size. Other numerical methods promising high resolution CBET simulations are under development, see for example Colaitis et al. (2019).

Two plasmon decay

Two plasmon decay (TPD) develops in a narrow region near one quarter of the critical density, where the laser frequency is equal twice the plasma frequency, see Fig. 10. The daughter plasma waves are excited in the plane of polarization of the pump wave and they are spatially localized. Consequently, TPD is an absolute instability—the daughter wave amplitudes grow in time and saturate due to nonlinear effects: secondary parametric decay, electron trapping or density profile modification.

TPD is an electronic instability with a high growth rate, $\gamma_{\text{TPD}} \approx \frac{1}{4} k_{\text{las}} v_{te}$, which corresponds to a growth time of typically less than one tenth of a picosecond. Electron collisions are not sufficient to stabilize such a fast growth, but TPD is sensitive to dephasing due to the density inhomogeneity. Thus, the TPD threshold is proportional to the density gradient:

$$v_{\text{las,th}}^2 / v_{te}^2 = 12 / k_{\text{las}} L_n \quad (53)$$

where $v_{te} = (T_e/m_e)^{1/2}$ is the electron thermal velocity and L_n is the density scale length at one quarter on the critical density. The TPD threshold can be written in practical units as:

$$I_{\text{TPD,th}} = 8.2 T_e L_n^{-1} \lambda_{\text{las}}^{-1} 10^{15} \text{ W cm}^{-2} \quad (54)$$

where the electron temperature at one quarter of the critical density is in keV, and L_n and λ_{las} are in microns. For the typical plasma temperature in the corona of 2–4 keV and a density scale length of 300–500 μm , the TPD threshold is in the range of several $10^{14} \text{ W cm}^{-2}$ and it is routinely excited in integrated experiments conducted on the Omega laser facility. It is, however, suppressed by SRS at larger energies in the experiments conducted on NIF, as demonstrated by Rosenberg et al. (2018).

TPD corresponds to excitation of a broad spectrum of plasma waves, from $k_p \sim k_{\text{las}}$ to the Landau damping limit, $k_p \sim 0.3 \lambda_D^{-1}$. They are efficiently coupled to electrons and produce a hot population with an effective temperature, $T_{h,\text{TPD}}$, and energy conversion factor, η_{TPD} , characterized in a series of numerical simulations by Vu et al. (2012):

$$T_{h,\text{TPD}} \approx 15.5 + 17.7 \zeta \text{ keV}, \quad \eta_{\text{TPD}} \approx 2.6 \times 10^{-2} \left(1 - \exp\left(-\sqrt{\xi - 1}\right) \right) \quad (55)$$

where $\zeta = I_{\text{las}}/I_{\text{TPD,th}}$. Typically, a few percent of laser energy is transferred to hot electrons with characteristic energy of the order of 100 keV. These electrons are considered as a serious threat for the direct drive implosions. It is, however, observed that TPD is suppressed in large scale experiments by the competing instability—SRS.

Stimulated Raman scattering

Stimulated Raman scattering (SRS) corresponds to a decay of the incident laser wave into another electromagnetic wave and a daughter electron plasma wave. The instability temporal growth rate, $\gamma_{\text{SRS}} \approx \frac{1}{4} k_{\text{las}} v_{\text{las}} (\omega_{pe}/\omega_s)^{\frac{1}{2}}$ where $\omega_s = \omega_{\text{las}} - \omega_{pe}$ is the frequency of scattered wave, is comparable to that of TPD, but in an inhomogeneous plasma it can be excited in a broad density range from one quarter of the critical density down to a few percent of the critical density, see Fig. 10. The minimum density is defined by the Landau damping of the daughter plasma wave.

SRS is a convective instability at densities below the quarter critical density. The resonance conditions for a given scattered wave frequency can be fulfilled in a narrow zone depending on the density scale length. The spatial detuning is defined by the plasma wave dispersion, $v_{g1} \Delta k_{\text{res}}' \approx d\omega_{pe}/dz = \omega_{pe}/2L_n$. Then, for scattering in the backward direction, according to Eq. (51), the SRS spatial gain reads:

$$G_{\text{SRS}} = \frac{\pi}{4} \frac{v_{\text{las}}^2}{c^2} \frac{k_{\text{las}}^2}{k_s} L_n \quad (56)$$

The wave number of the scattered wave, $k_s = (\omega_{\text{las}}/c) \sqrt{1 - 2\omega_{pe}/\omega_{\text{las}}}$, decreases with the plasma density and, consequently, the gain coefficient increases. This expression is not valid near one quarter of the critical density, where the group velocity of the

scattered wave goes to zero and the WKB approximation used in deriving Eq. (51) fails. At this particular density, SRS becomes an absolute instability, with the threshold lower by a factor of $(k_{\text{las}} L_n)^{1/3}$ than the threshold of the convective SRS, see Liu et al. (1974). In practical units, the SRS threshold near one quarter of the critical density can be written as

$$I_{\text{SRS,th}} = 100 L_n^{-4/3} \lambda_{\text{las}}^{-2/3} 10^{15} \text{ W cm}^{-2} \quad (57)$$

where the laser wavelength and the density scale length are in microns. It is quantitatively comparable to the TPD threshold (54), but the dependence of the density scale length and temperature is different. The TPD threshold is lower at lower temperatures and shorter plasma scale lengths, while the absolute SRS is excited at higher temperatures and in larger plasmas. Side scattering SRS is also an absolute instability below the quarter critical density.

Nonlinear saturation of SRS has been investigated in a large number of numerical simulations. Compared to TPD, absolute SRS saturates at a higher level, reflecting about 10–15% of the incident laser energy in the spectral domain around one half of the laser frequency. It also converts a similar amount of laser energy into a flux of forward propagating hot electrons. The energy distribution of such hot electrons can be approximated by an exponential distribution in energy with a characteristic temperature of 30–50 keV, as shown by Klimo et al. (2014), which is significantly lower than the effective temperature of TPD-generated hot electrons. The dominant role of the absolute SRS instability in hot electron generation at laser intensities exceeding $10^{15} \text{ W cm}^{-2}$ has also been confirmed in experiments by Theobald et al. (2017) and Rosenberg et al. (2018).

Electron energy transport

Laser energy deposited in the underdense plasma, $n_e \leq n_{\text{cr}}$, is transported to the ablation zone at the surface of a solid shell by electrons and radiation, see Fig. 2. Bremsstrahlung emission from the underdense plasma is much smaller than the laser energy flux, so that the electron heat flux dominates. However, it has been recognized at an early stage in ICF research that the electron energy flux in the conduction zone cannot be described by the classical Spitzer heat conductivity, $\mathbf{q}_{\text{SH}} = -\kappa_{\text{SH}} \nabla T_e$ (28). The absorbed energy flux of the order of $10^{15} \text{ W cm}^{-2}$, with a temperature decreasing from a few keV to a few eV, implies that the thickness of the conduction zone has to be comparable to the electron mean free path. Thus, the energy flux in the conduction zone is nonlocal and its appropriate description is one of the permanent preoccupations in ICF modeling.

As the full kinetic description of electron transport is incompatible with the hydrodynamic model, several simplified descriptions have been developed. The most simple approach consists of limiting the Spitzer heat flux with a constant fraction f_{fs} of the free streaming electron energy flux:

$$\mathbf{q}_e = \min \left\{ -\kappa_{\text{SH}} \nabla T_e, -f_{\text{fs}} n_e v_{te} T_e \nabla T_e / |\nabla T_e| \right\} \quad (58)$$

This model, however, is oversimplified, while many experimental observations may be simulated with a hydrodynamic code by choosing an appropriate value of flux limit, the chosen values of f_{fs} vary in a broad range from 0.01 to 0.5, depending on the numerical scheme and physics studied in a particular experiment.

Another model of nonlocal transport proposed by Luciani et al. (1983), describes the electron heat flux at a point, z , in plasma as a convolution of Spitzer fluxes originated at another points, z' , with a kernel, $w(z, z')$, localized on a distance comparable to the electron mean free path, $\lambda_e = \alpha(Z + 1)^{1/2} v_{te}/v_{ei}$:

$$q_e = - \int dz' w(z, z') q_{\text{SH}}(z'), \quad \text{where } w(z, z') = \frac{1}{2} \lambda_e^{-1}(z') \exp \left(- \left| \int_z^{z'} dz'' \lambda_e^{-1}(z'') \right| \right) \quad (59)$$

Comparison of this model with a full kinetic Fokker-Planck simulation shows a good agreement for the numerical factor $\alpha = 32$. Such a large value of the numerical coefficient is explained by the fact that the electrons contributing the most to the energy transport have a velocity 3–4 times larger than the thermal velocity. Their collision length scales as the fourth power of velocity and, consequently, the delocalization length increases by a factor of ≥ 30 compared to the mean free path of a thermal electron.

This nonlocal transport model (with an improved kernel defined in Fourier space) has found applications in describing parametric instabilities, in particular, SBS and filamentation, in a weakly collisional plasma, see Bychenkov et al. (2000). It is not, however, used in hydrodynamic modeling for two reasons. Firstly, such an integral representation of the heat flux is not compatible with a differential form of hydrodynamic equations, and the integral form of Eq. (59) strongly penalizes the performance of numerical simulations. Secondly, this model is intrinsically one-dimensional, which is not sufficient for modeling of three dimensional ICF implosions.

The most successful nonlocal model is that proposed by Schurtz et al. (2000), called the SNB model, which is based on the multigroup approach. Similarly to the Spitzer and Härm approach, this model starts from the approximation of a small anisotropy of the electron distribution function, $f_e(\mathbf{v}, \mathbf{r}) = f_0(v, \mathbf{r}) + (\mathbf{v}/v) \cdot \mathbf{f}_1(v, \mathbf{r})$, where $f_1 \ll f_0$, and uses a simplified BGK form of the collision integrals with the velocity-dependent electron-ion $\nu_{ei}(v)$ and electron-electron $\nu_{ee}(v)$ collision frequencies. Consequently the stationary Fokker-Planck equation is written in the following form:

$$\frac{v}{3} \nabla \cdot \mathbf{f}_1 - \frac{e\mathbf{E}}{3m_e v^2} \cdot \frac{\partial(v^2 \mathbf{f}_1)}{\partial \mathbf{v}} = -r \nu_{ee}(f_0 - f_M) \quad (60)$$

$$v \nabla f_0 - \frac{eE}{m_e} \frac{\partial f_0}{\partial v} = -\frac{\nu_{ei}}{\xi} f_1 \quad (61)$$

Here, the coefficients, $r \sim 1$ and $\xi(Z) = (Z + 0.24)/(Z + 4.2)$, account for the contribution of electron-electron collisions and the self-consistent electric field, E , is defined by the zero current condition, $\mathbf{j} = -4\pi e \int_0^\infty dv v^3 \mathbf{f}_1 = 0$. In contrast to the Spitzer-Härm approach, where the isotropic part of the electron distribution is assumed to be a Maxwellian function, f_M , with density, n_e , and temperature, T_e , depending on the spatial coordinate, the SNB model accounts for the deviation of f_0 from f_M . The solution is constructed in three steps. Firstly, Eq. (61) is solved for $\mathbf{f}_1$ with $f_0 = f_M$. Defining the electric field from the zero current condition, one obtains the Spitzer-like expression for the anisotropic part of electron distribution function:

$$\mathbf{f}_{1M} = -\xi \frac{v}{\nu_{ei}} \left(\frac{m_e v^2}{2T_e} - 4 \right) f_M \frac{\nabla T_e}{T_e} = -\left(\frac{m_e v^2}{2T_e} - 4 \right) g_1 \quad (62)$$

This is the integrand of the classical collisional heat flux, $\mathbf{q}_{SH} = (2\pi m_e/3) \int_0^\infty dv v^5 \mathbf{f}_{1M}$. The term in the parenthesis in (62) accounts for the balance between the current transported by hot electrons and the return current of cold electrons. In the second step, this expression for the anisotropic part of the electron distribution function is used to calculate the corrections $\delta f_0 = f_0 - f_M$ and $\delta \mathbf{f}_1 = \mathbf{f}_1 - \mathbf{f}_{1M}$:

$$r\nu_{ee}\delta f_0 + \frac{v}{3} \nabla \cdot \delta \mathbf{f}_1 = \frac{v}{3} \nabla g_1, \quad v \nabla \delta f_0 = -\nu_{ei}^* \delta \mathbf{f}_1 \quad (63)$$

This set of equations follows from (60), (61) with several simplifying assumptions. The return current and the electric field are neglected on the right hand side of first equation and the collision frequency of hot electrons in the second equation is corrected by the electric field contribution to the friction force, $\nu_{ei}^* = \nu_{ei}/\xi + 2e|E|/m_e v$, with the first order electric field. Then, in the third step, a correction to the electron heat flux is calculated: $\mathbf{q} = \mathbf{q}_{SH} + \delta \mathbf{q}$, where $\delta \mathbf{q} = (2\pi m_e/3) \int_0^\infty dv v^5 \delta \mathbf{f}_1$.

In spite of empirical modifications in the set of equations for the perturbation of the electron distribution function (63), the SNB model has demonstrated a very good performance in a semi-collisional plasma, where the electron-ion mean free path is smaller than a few tenths of the characteristic electron temperature length, $L_T = T_e/|\nabla T_e|$. Modification of the isotropic part of the electron distribution function in the velocity range $(1-10) v_{te}$ was found to be the major cause of the heat flux limitation. A diffusive form of the kinetic equation (63) enables its easy implementation in the hydrodynamic codes, so that the transport simulations are performed inline at each time step.

This model is implemented in many ICF hydrodynamic codes. Fig. 11 shows the performance of the SNB nonlocal model compared to the Spitzer-Härm heat flux and several other models for two representative tests. Firstly, one considers small amplitude temperature modulations, $T_e(z) = T_{e0} + \Delta T_e \sin kz$, with amplitude less than 1%. Panel A shows reduction of the thermal conductivity, defined as $q_e = -\kappa(k)k\Delta T_e \cos kz$, compared to the Spitzer thermal conductivity, see also Brodrick et al. (2017). Points indicate

Fig. 11 Performance of the nonlocal transport model: (A) Ratio of the heat transport coefficient, κ , to the value calculated with the Spitzer-Härm theory, κ_{SH} , for the periodic temperature modulations in a plasma with the ion charge $Z = 1$: Points are the results of kinetic simulations; black line—a theoretical fit; red and yellow lines—SNB model with two correction coefficients $r = 2$ and 3, respectively. (B) Calculations of the electron heat flux, q_e , across a steep temperature profile varying from 1 to 5 keV over a characteristic length of $50 \mu\text{m}$ with the electron mean free path of $\sim 3 \mu\text{m}$. Yellow line shows the temperature profile, $T_e(z)$; black line— q_e calculated with the SNB model; blue line—Spitzer heat flux, q_{SH} ; red line— q_e calculated with the flux limit model with $f = 0.075$. For more details see Brodrick JP, Kingham RJ, Marinak MM, et al. (2017) Testing nonlocal models of electron thermal conduction for magnetic and inertial confinement fusion applications. *Physics of Plasmas* 24: 092309. doi:10.1063/1.5001079.

the results of Fokker-Planck calculations, while red solid and dotted lines show the results of the SNB model with two different correction coefficients, $r = 2$ and 3 . A notable deviation starts already at very large wavelengths, $k\lambda_{ei} \sim 0.01$, and the SNB model provides sufficiently accurate results up to $k\lambda_{ei} \sim 0.2$ – 0.3 . This collisionality range is pertinent for ICF. By contrast, the SNB model fails in the collisionless limit, $k\lambda_{ei} \geq 1$, where κ scales as $1/k$.

Fig. 11b shows performance of the SNB model in the case of a large temperature variation from 1 to 5 keV over the characteristic length of 50 μm in a plasma with $Z = 1$ and an electron mean free path of 3 μm . In this case, the Spitzer heat flux is reduced by 40%, which can be accounted for by the flux limiter model with $f = 7.5\%$. However, the spatial profile of heat flux is not reproduced. The SNB model shows an enhancement of the heat flux in a cold plasma, which is produced by energetic electrons and cannot be reproduced with a simple flux limiter. Recent studies by Brodrick et al. (2017) confirmed a good agreement of the SNB model with full kinetic simulations in a broad range of plasma parameters.

This good agreement is, however, limited to cases without external magnetic field. A nonlocal transport in the presence of a magnetic field is not well described by the nonlocal models. This is still an open question. The BGK form of the collision integral is not adequate to describe the joint variation of the temperature and magnetic field profile in a plasma. An advanced kinetic model with a more accurate representation of the electron-electron collisions and entropic closure proposed by Del Sorbo et al. (2017) could be a promising option, but it is not yet sufficiently developed. Such a kinetic model can also be used for describing the energy transport by electrons generated in the plasma corona by parametric instabilities. At present, these hot electrons are described in a Monte Carlo or continuous slowing down approximation, which does not account for self-consistent electric and magnetic fields and thus is not sufficiently accurate.

Relativistic laser pulses

Conventional ICF approaches, both direct and indirect drive, are considering laser energy deposition on a nanosecond time scale and ablation pressures in the range of 100 Mbar. This implies the use of laser intensities in the range of 10^{14} – $10^{15} \text{ W cm}^{-2}$ at a wavelength of 0.35 μm (corresponding to the third harmonic of the Nd:glass laser). The physics of laser-plasma interactions in these conditions is non-relativistic as the electron quiver energy in the laser electric field is in the hundred electron-volt range, more than three orders of magnitude smaller than the electron rest energy. There are, however, alternative approaches to inertial fusion, which aim to create an ignition spot by a direct deposition of laser energy in the compressed fuel, see chapter 12.20 “ICF physics principles” and Kemp et al. (2014), Robinson et al. (2014), Norreys et al. (2014), and Fernández et al. (2014). As discussed in section “Hot spot energy balance”, the hot spot energy at ignition is about 10 kJ and the stagnation time is about 10 ps. Thus, the required laser power is in the range of several petawatt. When focused in a spot of a size less than 100 μm , the laser intensities exceed typically $10^{19} \text{ W cm}^{-2}$ at a wavelength of 1 μm . The electron quiver energy under such conditions is in the mega-electron-volt scale, and thus the laser plasma interaction is relativistic.

The laser radiation cannot directly access the compressed core, and the interaction process proceeds in two (or three) steps: firstly, the intense laser pulse is absorbed and its energy is transferred to a group of relativistic electrons; secondly, these electrons transport this energy to a dense fuel and deposit it preferentially in a small volume thus raising the pressure and temperature locally to the ignition conditions. This scheme is known as electron fast ignition, see Tabak et al. (1994). Alternatively, in the fast ion ignition scheme, see Bychenkov et al. (2001) and Roth et al. (2001), the laser-accelerated electrons transfer their energy to ions, which then penetrate to the dense core and create the ignition spot.

An energy transfer from laser to electrons is very efficient at relativistic intensities. Extensive numerical simulations and experiments show that electrons acquire an exponential energy distribution with an effective temperature, T_{eh} , comparable to their quiver energy in the laser electric field, see Wilks et al. (1992):

$$T_{eh} \approx m_e c^2 \left(\sqrt{1 + a_{\text{las}}^2/2} - 1 \right) \quad (64)$$

where $a_{\text{las}} = eE_{\text{las}}/m_e\omega_{\text{las}}c$ is the dimensionless laser amplitude. The conversion efficiency of laser energy to electrons increases with laser intensity from about 20–30% at a near relativistic intensity of $I_{\text{las}} \sim 1.5 \times 10^{18} \text{ W cm}^{-2}$ (corresponding to $a_{\text{las}} \sim 1$) to up to 80% at $a_{\text{las}} \sim 10$ – 20 .

There is, however, a serious caveat with fast electron ignition. While the electrons are accelerated predominantly in the laser propagation direction, the electron bunch entering into the dense plasma becomes strongly divergent, representing a cone with a characteristic opening angle of 30–40 degrees. This is explained by the electromagnetic Weibel-like instability excited by the return current. Indeed, a beam of relativistic electrons carrying an energy flux of $q_e \sim 10^{19} \text{ W cm}^{-2}$ also carries an enormous current $j_e \sim 10^{12} \text{ A cm}^{-2}$. It is compensated by the return current of plasma electrons ($j_{\text{ret}} = -j_e$) moving in the opposite direction with a velocity, $v_e \sim 10^{-3}c$. The growth rate of an electromagnetic instability, $\sim \omega_{pe}v_e/c$, belongs to the subpicosecond domain and results in a fast beam filamentation and the generation of a strong magnetic field producing a significant beam divergence.

A strong return current in the plasma leads also to an enhanced dissipation rate of the relativistic electron beam, as shown by Bell et al. (1997). In contrast to the laser accelerated relativistic electrons, the plasma electrons are collisional and the return current produces a strong electric field, $E_s = j_e/\sigma_e$, inversely proportional to the plasma conductivity, σ_e . For a typical value of plasma conductivity of 10^7 S , this electric field attains values of about 1 GV m^{-1} , thus slowing down the relativistic electrons over a distance of 1 mm. Moreover, according to the Faraday’s law, the curl of this electric field results in the generation of a magnetic field with a growth rate of about 100 T ps^{-1} that may deflect the electrons and prevent their focusing in a small spot.

The electrons are not well suited to the creation of a compact hot spot. As explained in section “Hot spot energy balance”, one of the conditions for fuel ignition is that the hot spot areal density is comparable with the stopping range of α -particles produced in DT fusion reactions, which is on the order of $0.2\text{--}0.4\text{ g cm}^{-2}$. This areal density corresponds to the stopping range of electrons with energy less than 1 MeV. However, according to Eq. (64), such relatively low energy electrons are produced at a laser intensity of several units of 10^{18} W cm^{-2} , which is not sufficient for providing the petawatt power needed for ignition. Thus, relativistic electron heating inevitably creates a hot spot, which is too large. Although recent integrated experiments on the Japanese laser system GekkoXII-LFEX by Sakata et al. (2018) have demonstrated an efficient guiding of a laser-generated electron beam and energy deposition in the compressed target, the use of relativistic electrons for ignition of fusion reactions remains problematic.

Energetic protons are better suited for creation of a compact hot spot. Their stopping length is shorter than that of electrons and can be adjusted to the optimum size of the ignition spot, as each proton carries more than ten times more energy than an electron and, therefore, less protons are needed. In addition, protons can be better focused in a small spot. However, laser acceleration of protons is less efficient and methods of proton acceleration are less developed.

Laser-ion acceleration proceeds in two steps: firstly, electrons are accelerated in the laser pulse and then they transfer their energy to ions. The most reliable method, called target normal sheath acceleration (TNSA), involves ion acceleration in a plasma rarefaction wave driven by hot electrons. It operates via an interaction of intense and short laser pulses with thin solid foils. The electrons accelerated in a laser pulse on the front surface penetrate the foil and create a Debye sheath, $\lambda_{Dh} = (\epsilon_0 T_{eh}/e^2 n_{eh})^{1/2}$, at the rear surface. The potential drop, $\Phi_{es} \sim T_{eh}/e$, could be as large as 10 MV over the thickness of a few microns, thus creating an electrostatic field, $E_{es} \approx \Phi_{es}/\lambda_{Dh}$, exceeding 1 GV m^{-1} . This field instantaneously ionizes the atoms at the rear surface and accelerates the ions, preferentially protons as they have the largest charge-to-mass ratio, to energies of up to a few times the electrostatic potential. Extensive reviews of the ion acceleration can be found in Daido et al. (2012) and Macchi et al. (2013).

Numerical simulations and experiments show that the ions are accelerated normally to the rear target surface in a narrow cone of $10\text{--}20$ degrees; their energy distribution is broad, exponential-like, with an effective temperature of the order of the hot electron temperature (64). So laser intensities on the order of 10^{20} W cm^{-2} are needed for ion acceleration to tens of MeV energies. Two major obstacles for using the TNSA ions for fast ignition are: (i) relatively small efficiency of ion acceleration, typically a few percent of laser energy is transferred to ions; and (ii) relatively small number of accelerated ions, typically $10^{12}\text{--}10^{13}$ particles per shot. These issues are related to the very small depth of penetration of the sheath electrostatic field in a solid target, which is less than one tenth of micron. In contrast to electron fast ignition, no integrated experiments on ion fast ignition have been performed yet. This could be a challenge for the next generation of high-power, high-energy laser facilities.

Glossary

Areal density The product of the plasma density and thickness.

Ignition Ignition occurs when the yield amplification from the alpha heating exceeds twenty.

Plasma A plasma is a quasineutral gas of charged and neutral particles which exhibits collective behavior due to the long-range electromagnetic forces.

Introduction

In the last seven decades research and development of controlled thermonuclear fusion has been pursued in the laboratory as an alternative energy resource to fossil fuels using magnetically-confined plasmas (Meade, 2009), such as the tokamak (Rutherford, 1980). Since the advent of the laser in the 1960s, inertial confinement fusion schemes using lasers have been investigated (Nuckolls et al., 1972; Kidder, 1974, 1976; Lindl et al., 1992). In the last few decades, inertial confinement fusion using pulsed power has been pursued (Slutz et al., 2010; Gomez et al., 2021). Thermonuclear fusion of the hydrogen isotopes deuterium (D) and tritium (T) involves nuclear fusion of the ions in a high-temperature plasma, where the thermal energy of the ions in the plasma overcomes their long-range Coulomb repulsion and the short-range nuclear force fuses the ions. The high fusion reaction rate of deuterium and tritium (i.e., $D + T \rightarrow {}^4\text{He} + n$) relative to other fusion reactants makes it a practical fuel choice for laboratory fusion plasmas and the majority of fusion research has used this fuel. Nuclear energy is released in the reaction, since the DT fusion converts almost 0.4% of the mass of the hydrogen isotopes into energy through Einstein's mass-energy relationship, $\Delta E = \Delta mc^2$, where ΔE is the energy liberated in the nuclear fusion reaction, Δm is the difference in the mass of the reactants and the fusion products, and c is the speed of light. The alpha particle (${}^4\text{He}$) and the neutron fusion products have birth energies of 3.5 and 14.1 MeV, respectively. Thermonuclear fusion plasmas are designed to absorb the energy of the alpha particle to further increase the plasma temperature leading to more fusion reactions (i.e., alpha heating). The viability of energy production in a fusion plasma is quantified by the Lawson criterion, which compares the rate of energy generation from nuclear fusion to the rate of energy loss in the plasma (Lawson, 1957). For ICF, these loss mechanisms include radiation, thermal conduction, and hydrodynamic expansion. Future inertial fusion power plants would use the energetic neutrons to bombard a blanket containing lithium surrounding the fusion plasma to breed tritium fuel using the following nuclear reaction: $n + {}^6\text{Li} \rightarrow {}^4\text{He} + T$ (Atzeni, 2021). The energy that the neutrons deposit in the blanket can be extracted with a heat exchanger and used boil water for a steam turbine to generate electricity. The three main approaches of inertial confinement fusion are laser direct drive (Goncharov et al., 2014, 2017; Craxton et al., 2015; Regan et al., 2016, 2019; Bose et al., 2016; Campbell et al., 2017, 2021; Gopalaswamy et al., 2019; Campbell, 2021), laser indirect drive (Moses et al., 2009; Glenzer et al., 2010; Meezan et al., 2010; Michel et al., 2010; Haan et al., 2011; Edwards et al., 2011; Landen et al., 2011; Edwards et al., 2013; Hurricane et al., 2014, 2019a,b, 2021; Meezan et al., 2015; Le Pape et al., 2018; Landen et al., 2020; Patel et al., 2020; Town, 2020; Zylstra et al., 2021; Landen et al., 2021), and magnetic direct drive (Slutz et al., 2010, 2018; Sinars et al., 2020; Gomez et al., 2021). This chapter concentrates on the current status of the experimental physics in inertial confinement fusion involving lasers, while magnetic direct drive is covered elsewhere (Gomez et al., 2021).

Laser-driven inertial confinement fusion creates thermonuclear conditions in the laboratory by irradiating a spherical target containing a layer of thermonuclear fuel (Gibson et al., 2009; Johal et al., 2009; Harding et al., 2005, 2018) as shown in Fig. 1 with high-intensity lasers or X-rays (Atzeni, 2021; Tikhonchuk, 2021). The physical dimensions and composition of the ablator depends on the energy incident on the target and the photon wavelength of the driver. Inertial confinement fusion implosions are analogous to a spherical rocket, where the rocket fuel (the ablator) is energized by the incident driver energy and the DT fuel is the payload. The initial pursuit of laser fusion involved laser direct drive, where the outer surface of the target is uniformly irradiated with multiple, temporally-shaped laser beams having a peak, overlapped intensity of $<10^{15}$ watts/cm² on the nanosecond time scale. As mentioned above, the resulting laser-ablation process causes the target to accelerate and implode via the rocket effect, reaching

Fig. 1 Schematic of a laser-driven inertial confinement fusion target for central hot-spot ignition, consisting of an ablator surrounding a cryogenic layer of deuterium (D) and tritium (T). The central void contains DT gas.

a peak implosion velocity in the 300 to 500 km/s range depending on the implosion design (Tikhonchuk, 2021). In the early days of inertial confinement fusion research, challenges with nonuniformities in the laser drive incident on the target surface motivated the development of laser indirect drive, whereby the laser energy is converted to X-rays in a high-atomic number radiation case, called a hohlraum, with a near-Planckian spectrum having a temperature of about 300 eV to drive the ablation process (Lindl et al., 1992, 2004; Lindl, 1995, 1998). The two laser-driven, inertial confinement fusion techniques are highlighted schematically in Fig. 2. The spherical concentric layers of a laser-direct-drive inertial confinement fusion target typically consist of a central region of a near equimolar DT vapor surrounded by a cryogenic DT-fuel layer and a thin, nominally plastic (CH) layer, called the ablator (see Fig. 1). The laser-indirect-drive target is similar except the ablator is thicker, due to the efficient x-ray driven ablation, and has multiple concentric layers designed to optimize the implosion (Lindl, 1998; Town, 2020; Tikhonchuk, 2021). In both cases, as the DT-fuel layer decelerates, the initial DT vapor and the fuel mass thermally ablated from the inner surface of the ice layer are compressed and form a central hot-spot plasma, in which fusion reactions occur for a few tenths of a nanosecond around stagnation. The energy coupling from the laser to the hot-spot plasma can be adversely affected by laser plasma instabilities (Kruer, 2003; Tikhonchuk, 2021), hydrodynamic instabilities (Tikhonchuk, 2021), and low- and high-mode drive asymmetries (Town, 2020; Campbell, 2021; Tikhonchuk, 2021). Inertial confinement fusion relies on the 3.5 MeV DT-fusion alpha particles depositing their energy in the hot-spot plasma, causing the hot-spot temperature to rise sharply and a thermonuclear burn wave to propagate out through the surrounding nearly-degenerate, cold dense DT fuel as highlighted in Fig. 3, producing significantly more energy than was used to heat and compress the fuel. The inertia of the compressed DT shell confines the hot-spot plasma for a timescale that is long enough for alpha heating to trigger the ignition instability and achieve energy gain (Town, 2020; Campbell, 2021; Tikhonchuk, 2021; Atzeni, 2021). A burning plasma has a yield amplification due to alpha heating greater than 3.5 (Betti et al., 2015; Hurricane et al., 2019b). Alpha amplification is a metric to describe the increase in overall fusion beyond that due to the hydrodynamic work done during the implosion. An ignited plasma has a yield amplification due to alpha heating in the range of 15 to 25 depending on the implosion design (Christopherson et al., 2019). The total fusion yield depends on the burn up fraction of the DT fuel, which is

Fig. 2 Schematics highlighting the two laser-driven, inertial confinement fusion techniques: laser direct drive (left panel) and laser indirect drive (right panel).

Fig. 3 Inertial confinement fusion relies on the 3.5 MeV DT-fusion alpha particles depositing their energy in the hot-spot plasma, causing the hot-spot temperature to rise sharply and a thermonuclear burn wave to propagate out through the surrounding nearly-degenerate, cold dense DT fuel as highlighted with the spatial profiles of the temperature and density.

a function of the total areal density of the compressed DT fuel (Lindl, 1998). The onset of central-hot-spot ignition is predicted to occur when the product of the temperature and areal density of the hot-spot plasma reach a minimum of $5 \text{ keV} \times 0.3 \text{ g/cm}^2$ (Betti et al., 2002; Lindl et al., 2004; Atzeni and Meyer-ter-Vehn, 2004). A generalized Lawson ignition parameter (hot-spot pressure $\times$ hot-spot confinement time) is used to quantify the proximity to ignition, where a value of unity corresponds to ignition (Betti et al., 2015). Here the pressure and confinement time are estimated without accounting for alpha heating to assess the pure hydrodynamic performance of the implosion. The ignition threshold factor (Spears et al., 2012; Lindl et al., 2014, 2018) used for laser indirect drive implosions is related to the generalized Lawson ignition parameter (Patel et al., 2020).

Central-hot-spot ignition is presently the main line research of laser-driven inertial confinement fusion. Other laser driven inertial confinement fusion techniques under investigation include shock ignition (Betti et al., 2007; Atzeni et al., 2014), fast ignition (Tabak et al., 1994; Kodama et al., 2002; Theobald et al., 2011, 2014), and volumetric ignition with multiple-shell targets (Varnum et al., 2000; Amendt et al., 2002; Molvig et al., 2016; Montgomery et al., 2018; Hu et al., 2019).

This chapter concentrates on the laser-driven central-hot-spot ignition experiments involving implosions of layered DT cryogenic targets (Gibson et al., 2009; Johal et al., 2009; Harding et al., 2005, 2018) conducted at the 192-beam, 2.1-MJ, 500-TW, 351-nm National Ignition Facility (Campbell and Hogan, 1999; Spaeth et al., 2016) and the 60-beam, 30-kJ, 30-TW, 351-nm OMEGA Laser System (Boehly et al., 1997). These lasers are shown in Fig. 4 and described elsewhere (Finnegan, 2021). A primary goal of the National Ignition Facility is to achieve ignition and modest gain using the laser-indirect-drive ignition approach first and then laser direct drive.

Laser-indirect-drive ignition-scale implosions have been performed on the National Ignition Facility since 2009 (Moses et al., 2009; Glenzer et al., 2010; Meezan et al., 2010; Michel et al., 2010; Haan et al., 2011; Edwards et al., 2011, 2013; Landen et al., 2011, 2020, 2021; Hurricane et al., 2014, 2019a, b, 2021; Meezan et al., 2015; Le Pape et al., 2018; Patel et al., 2020; Town, 2020; Zylstra et al., 2021). The laser-indirect-drive implosions on the National Ignition Facility are designed to investigate alpha heating, burning plasma, and ignition target designs (Hurricane et al., 2014, 2019a, b, 2021; Patel et al., 2020; Town, 2020; Zylstra et al., 2021). These experiments have demonstrated alpha heating and are accessing the burning plasma regime, which is an encouraging development in the pursuit of the grand research challenge of ignition.

Several facility enhancements are required on the National Ignition Facility to conduct laser-direct-drive ignition-scale implosions. Progress made with laser direct drive over the last decade motivates laser direct drive implosions on the National Ignition Facility (Goncharov et al., 2014, 2017; Craxton et al., 2015; Regan et al., 2016, 2019; Bose et al., 2016; Campbell et al., 2017; Gopalaswamy et al., 2019; Campbell, 2021; Campbell et al., 2021), since laser direct drive increases the amount of energy coupled to the hot spot by a factor of several over the laser indirect drive, which enables increased mass in the hot spot, leading to a potential increase in the margin for ignition. Energy coupling from the laser to the implosion capsule is an important consideration in inertial confinement fusion. The larger imploded mass and increased coupled energy results in lower required convergence and hot-spot pressure and the possibility of achieving MJ yields at implosion adiabats greater than three (Goncharov et al., 2014, 2016, 2017). The adiabat is the ratio of the pressure in the cold DT fuel to the Fermi-degenerate pressure, which is the minimum energy density due to the degeneracy of the electrons that can be achieved (Tikhonchuk, 2021). Understanding the laser and target physics requirements for ignition is important for the inertial confinement fusion research program on the National Ignition Facility and for the research and development of a next-generation laser facility designed to achieve a robust burning-plasma platform and high yield (i.e., $>200 \text{ MJ}$).

Fig. 4 Schematics of the 60-beam, 30-kJ, 30-TW, 351-nm OMEGA Laser System at the University of Rochester's Laboratory for Laser Energetics (LLE) and the 192-beam, 2.1-MJ, 500-TW, 351-nm National Ignition Facility at the Lawrence Livermore National Laboratory (LLNL).

Fig. 5 Schematics of the NIF target chamber with the blue circles highlighting the beam configuration for laser indirect drive (X-ray drive) and Polar Direct Drive (left panel) and the spherically-symmetric beam configuration for laser direct drive, called spherical direct drive (right panel) on the National Ignition Facility. The current beam configuration on the National Ignition Facility is optimized for laser indirect drive (left panel).

Although the beam configuration on the National Ignition Facility is optimized for laser indirect drive with a right circular cylindrical hohlraum by arranging the beams around the poles of the target chamber as illustrated with the blue circles in the left panel of Fig. 5, it can also be used for a variant of laser direct drive called Polar Direct Drive (Skupsky et al., 2004; Craxton et al., 2005; Craxton and Jacobs-Perkins, 2005; Cobble et al., 2012; Radha et al., 2012, 2013, 2016; Krashenninnikova et al., 2014; Hohenberger et al., 2015; Rosenberg et al., 2018; Marozas et al., 2018a, b). The optimal arrangement for laser direct drive with the beams uniformly distributed around the target chamber is highlighted with the blue circles in the right panel of Fig. 5, called spherical direct drive. Although the NIF target chamber has ports for spherical illumination, switching between these two beam geometries requires a major, resource-intensive engineering effort. The laser direct drive ignition approach on the National Ignition Facility is Polar Direct Drive for the next five to ten years. In the Polar Direct Drive configuration, which is also studied in experiments on OMEGA using only 40 beams (Marshall et al., 2006, 2016; Radha et al., 2012), a subset of the beams is repointed toward the equator of the target to recover the spatial uniformity of the on-target, overlapped laser-drive intensity. Several of the key physics aspects of laser direct drive, including energy coupling, laser plasma instabilities, and hydrodynamic instabilities, at ignition-relevant scale lengths are studied on the National Ignition Facility using a polar-direct-drive configuration (Radha et al., 2013, 2016; Krashenninnikova et al., 2014; Hohenberger et al., 2015; Rosenberg et al., 2018; Marozas et al., 2018a, 2018b; Campbell, 2021).

Significant laser and cryogenic target upgrades are required to perform high-convergence (i.e., convergence ratio > 15), laser-direct-drive implosions using the polar-direct-drive configuration for burning plasma and ignition on the National Ignition Facility (Campbell, 2021). Planning is underway to implement these polar direct drive facility enhancements to the National Ignition Facility over the next 10 years (Campbell, 2021). Hot-spot formation for spherically symmetric, laser-direct-drive, DT-layered implosions is studied on the OMEGA laser system using hydrodynamically-scaled ignition targets (Nora et al., 2014; Goncharov et al., 2014; Regan et al., 2016; Bose et al., 2016; Gopalaswamy et al., 2019), since OMEGA does not have enough laser energy to assemble an ignition-scale hot-spot plasma. A primary goal of OMEGA is to investigate subscale laser-direct-drive implosions and the underpinning fundamental physics of implosion designs that are hydrodynamically equivalent (i.e., maintaining the same shell convergence, hot-spot pressure, shell adiabat, and implosion velocity) to burning plasma and ignition designs on MJ-scale lasers in both polar and spherical illumination geometries (Campbell, 2021).

This chapter presents a concise overview of the current status of the experimental physics research for central-hot-spot ignition using laser-driven inertial confinement fusion. More detailed descriptions can be found in recent review reports for laser direct drive (Campbell, 2021) and laser indirect drive (Town, 2020). The energy coupling from the laser to the hot-spot plasma and the degradation mechanisms to implosion performance from laser plasma instabilities, hydrodynamic instabilities, and low-mode drive and target asymmetries (Tikhonchuk, 2021) are discussed for the two laser-driven inertial confinement fusion approaches using central hot-spot ignition. Section “**Laser-Direct-Drive Research**” presents the performance of laser-direct-drive implosions on OMEGA that are hydrodynamically-scaled to the 2.0 MJ of laser energy on the National Ignition Facility (Goncharov et al., 2014; Igumenshchev et al., 2016; Regan et al., 2016; Bose et al., 2016; Gopalaswamy et al., 2019; Campbell, 2021; Campbell et al., 2021). These hydrodynamically-scaled, spherical direct drive implosions are predicted to achieve a threefold amplification in fusion yield due to alpha heating, corresponding to a total fusion yield of about 0.6 MJ (Gopalaswamy et al., 2019; Campbell, 2021). The energy-scaled, generalized Lawson ignition parameter (Betti et al., 2015; Bose et al., 2016) for laser direct drive implosions on OMEGA is approximately 0.75 (Campbell, 2021). The research and development of high-energy, solid-state laser drivers that mitigate laser-plasma instabilities and laser-beam imprint via enhanced spectral bandwidth to increase the implosion performance are also discussed in this chapter (Follett et al., 2018, 2019; Bates et al., 2018; Dorner et al., 2020). Section “**Laser Indirect Drive Research**” summarizes the progress of the laser-indirect-drive approach on the National Ignition Facility demonstrating alpha

heating and accessing the burning plasma regime with ~ 2 MJ of laser energy, corresponding to ~ 0.06 MJ of total fusion yield, and the quest for the ignition challenge (Moses et al., 2009; Glenzer et al., 2010; Meezan et al., 2010, 2015; Michel et al., 2010; Haan et al., 2011; Edwards et al., 2011, 2013; Landen et al., 2011; Hurricane et al., 2014; Le Pape et al., 2018; Hurricane et al., 2019a, b; Landen et al., 2020, 2021; Patel et al., 2020; Town, 2020; Zylstra et al., 2021; Hurricane et al., 2021). The generalized Lawson ignition parameter for laser-indirect-drive implosions on the National Ignition Facility is 0.75 (Patel et al., 2020). The path forward for ignition on the National Ignition Facility with laser indirect drive is also discussed.

Laser-Direct-Drive Research

As mentioned in the introduction, the high-intensity lasers are incident directly on the target for the laser-direct-drive approach. There are four stages to the resulting implosion: initial plasma formation, acceleration, deceleration, and stagnation, which are highlighted in Fig. 6 (Campbell, 2021; Tikhonchuk, 2021). Depending on the implosion design, the peak shell velocity at the end of the acceleration phase is in the 300–500 km/s range. After the laser ionizes the target surface and the coronal plasma is formed, the laser light is absorbed in the under-dense plasma via inverse Bremsstrahlung and a fraction of the absorbed energy flows to the ablation surface via electron thermal conduction. The coronal plasma typically absorbs 60–70% of the laser energy and hydrodynamic efficiency of converting that absorbed laser energy to inward kinetic energy of the shell via the rocket effect is about 9%. This gives a conversion efficiency of incident laser energy to shell kinetic energy of about 6% for laser direct drive. The laser ablation launches a shock wave into the target. As the coronal plasma forms, spatial nonuniformities in the laser irradiation can imprint on the ablation surface (i.e., laser imprint) and mass perturbations on the target from microscopic debris, the support stalk, and the fill tube seed the Richtmyer-Meshkov hydrodynamic instability (Richtmyer, 1960; Meshkov, 1969; Goncharov, 1999). The key target physics during the initial plasma formation are laser uniformity, laser absorption, energy coupling, ablation, shock propagation, laser imprint, and the Richtmyer-Meshkov hydrodynamic instability. The time history of the laser intensity on target, shown in the right panel of Fig. 6, is designed to minimize the rise in the entropy of the compressed shell, quantified by the shell adiabat, in order to minimize the amount of laser energy needed for ignition (Tikhonchuk, 2021). Although lower-adiabat ignition target designs require less laser energy to achieve ignition (Herrmann et al., 2001; Betti et al., 2002), they are more susceptible to hydrodynamic instabilities (Betti et al., 1998).

After the shock wave reaches the inside layer of the DT shell and the rarefaction wave returns to the ablation surface, the DT shell begins to accelerate (see Fig. 6). Mass perturbations at the ablation surface due to target defects and laser nonuniformities can seed the Rayleigh Taylor hydrodynamic instability (Rayleigh, 1945; Taylor, 1950; Cole et al., 1982). During the acceleration phase, as mentioned above, the intensity of the laser irradiation may exceed the thresholds to excite electron waves in the plasma via the Stimulated Raman Scattering or the Two Plasmon Decay instability and ion waves in the plasma via the Stimulated Brillouin Scattering (Kruer, 2003). Excitation of ion waves in the plasma can divert energy flow from the laser to the ablation front. In the cross-beam energy transfer process (Igumenshchev et al., 2010, 2012; Froula et al., 2012), nonabsorbed light that is reflected or scattered from its critical surface or refracted from the under-dense plasma acts as an electromagnetic seed for the stimulated Brillouin scatter of incoming (incident) light (Randall and Albritton, 1981). Cross beam energy transfer has been shown to reduce the target absorption and resulting ablation pressure of laser direct drive targets by as much as 40% on OMEGA (Igumenshchev et al., 2010, 2012, Froula et al., 2012) and 60% on polar direct drive targets for the National Ignition Facility (Radha et al., 2016). Excitation of electron waves

Fig. 6 (Left panel) The four stages of the laser direct drive implosion—initial plasma formation, acceleration, deceleration, and stagnation—and associated key target physics areas. The peak neutron production occurs at stagnation. (Right panel) The time history of the laser power (black curve) and the trajectory of the ablation surface of the imploding shell R_{abl} (lower blue curve) and the trajectory of the ablated CD/DT interface $R_{CD/DT}$ (upper blue curve).

can cause suprathermal electron generation, which has the detrimental effect of preheating the DT fuel and raising the adiabat (Rosenberg et al., 2018; Solodov et al., 2020; Tikhonchuk, 2021). Deviations from a spherical implosion or multidimensional effects can be caused by hydrodynamic instabilities and laser-plasma instabilities. The key target physics during the acceleration phase are laser uniformity, laser-plasma interactions, hot-electron preheating, energy coupling, Rayleigh-Taylor hydrodynamic instability, ablation, shock propagation, and multidimensional effects.

The displacement work that the converging DT shell performs on the nascent hot-spot plasma increases the hot-spot pressure and causes the DT shell to decelerate (see Fig. 6). The inner wall of the DT shell can become unstable to the Rayleigh-Taylor hydrodynamic instability (Tikhonchuk, 2021). Multidimensional effects are amplified during the deceleration phase and can lead to perturbations to the hot-spot plasma (Woo et al., 2018; Shah et al., 2020; Mannion et al., 2021). The key target physics during the deceleration phase are energy coupling, Rayleigh-Taylor growth, ablation, hot-spot formation, and multidimensional effects. The peak values of DT fusion yield and the compressed areal density can be limited at stagnation by hydrodynamic mixing of the ablator and DT ice layer with the hot-spot plasma at stagnation (see Fig. 6) and incomplete conversion of shell kinetic energy into internal energy of the hot spot due to low-mode asymmetries (Woo et al., 2018; Mannion et al., 2021). The key target physics at stagnation are energy coupling, residual kinetic energy, DT fusion yield, compressed areal density, multidimensional effects, and hydrodynamic mixing.

The performance of a laser direct drive ignition target depends on the implosion symmetry (Woo et al., 2018; Mannion et al., 2021), the hydrodynamic instabilities seeded by laser imprint and target features (e.g., microscopic surface debris, fill tube or stalk) (Igumenshchev et al., 2013), the laser-plasma instabilities in the coronal plasma (Kruer, 2003; Igumenshchev et al., 2010; Igumenshchev et al., 2012; Froula et al., 2012; Randall and Albritton, 1981; Rosenberg et al., 2018; Marozas et al., 2018, b; Kruschwitz et al., 2019; Turnbull et al., 2020a, b; Solodov et al., 2020; Tikhonchuk, 2021), and the fundamental material properties (i.e., equation of state, opacity, and conductivity) (Hu et al., 2011, 2015, 2017, 2018; Ding and Hu, 2017; Campbell, 2021). In the near term, mitigation strategies for laser plasma instabilities include laser (i.e., wavelength detuning) (Marozas et al., 2018a, Marozas et al., 2018b, Kruschwitz et al., 2019, Turnbull et al., 2020a, Turnbull et al., 2020b,) and target solutions (i.e., buried Si layer in ablator) (Solodov et al., 2020) that can be implemented on the National Ignition Facility. In the longer term the Laboratory for Laser Energetics is exploring broadband ultraviolet (351-nm) laser technologies to mitigate laser plasma instabilities (Follett et al., 2018, 2019; Bates et al., 2018) and laser imprint, leading to more stable implosions with a higher fraction of laser energy coupled to the hot spot. Recently, the Laboratory for Laser Energetics has demonstrated a significant breakthrough with a novel efficient broadband tripling scheme ($\Delta\omega/\omega > 1.5\%$, > 13 THz) (Dorrer et al., 2020). A staged plan has been devised to develop this new laser technology over the next few years for laser direct drive as well as laser indirect drive (Campbell, 2021).

As mentioned in the introduction laser and target upgrades are required on the National Ignition Facility to perform high convergence ($CR > 15$) polar-direct-drive implosions. The current laser-direct-drive research strategy for estimating the performance scaling from OMEGA to the National Ignition Facility in the absence of these upgrades starts from the theoretical scaling to the NIF, positing the same core conditions achieved on OMEGA can be reproduced at the NIF scale (i.e., the same pressure and scaled density and temperature) (Campbell, 2021). This scaling approximates conservatively that engineering target features (e.g., the stalk or the fill tube) and target-fabrication imperfections that degrade the implosion, scale with size. The impact of all the sources of degradation, including energy coupling, hot-electron preheat, target imperfections, and laser-drive asymmetry, expected at the National Ignition Facility scale are assessed and evaluated through dedicated laser plasma interaction and hydrodynamic experiments on the National Ignition Facility and OMEGA. A comparison of polar direct drive and spherical direct drive laser-irradiation geometries on OMEGA is investigated. The design parameter space available for the laser direct drive approach is determined, and the hydrodynamic scaling is verified within the energy range accessible to the OMEGA laser.

The performance of laser-direct-drive implosions on OMEGA that are hydrodynamically-scaled to the 2.0 MJ of laser energy on the National Ignition Facility assuming spherical direct drive (Goncharov et al., 2014; Regan et al., 2016; Bose et al., 2016; Gopalaswamy et al., 2019; Campbell, 2021; Campbell et al., 2021) were evaluated. The best performing hydrodynamically-scaled, spherical direct drive implosions are predicted to achieve a threefold amplification in fusion yield due to alpha heating, corresponding to a total fusion yield of 0.6 MJ of fusion yield (Gopalaswamy et al., 2019; Campbell, 2021). The energy-scaled, generalized Lawson ignition parameter (Bose et al., 2016) for laser direct drive implosions on OMEGA is approximately 0.75 (Campbell, 2021). A statistical approach was used to design and quantitatively predict the results of the highest-performing laser-direct-drive implosion on OMEGA, leading to tripling of the fusion yield (Gopalaswamy et al., 2019).

A 10-year plan with four physics goals is being developed to implement upgrades to the National Ignition Facility to optimize the performance of polar direct drive DT cryogenic implosion targets in the burning-plasma regime, and to understand the laser facility and target requirements (i.e., energy, power, size, beam smoothing, phase plates, and wavelength detuning) needed to achieve ignition and multi-MJ yield. The first physics goal is to optimize the symmetry of convergence ratio ≤ 10 , polar direct drive implosions of room-temperature DT-filled capsules using the current NIF capability and innovative target designs with a goal of achieving a 50-kJ fusion yield. The second physics goal is to improve with modest investment the energy coupling and symmetry for those implosions using wavelength detuning with beam remapping and dedicated polar direct drive phase plates. The third and fourth physics goals require significant modifications on the National Ignition Facility, including a laser direct drive cryogenic target-handling system and upgrades in laser beam smoothing, to increase the convergence ratio to 15 and then to 20 with polar direct drive DT cryogenic target implosions in order to achieve an alpha burner and to reach the burning-plasma regime (i.e., 1-MJ fusion yield), respectively.

Laser-Indirect-Drive Research

Ignition-scale implosions are being performed on the National Ignition Facility using laser indirect drive. As mentioned in the introduction, the challenges with nonuniformities in the laser drive incident on the target surface in the early days of inertial confinement fusion research motivated the development of laser indirect drive (Lindl et al., 1992, 2004; Lindl, 1995, 1998). The laser beams incident on the inner wall of the high-Z hohlraum wall (see right panel of Fig. 2) create an ablation plasma, which converts the laser energy to the x-ray drive (Lindl, 1998). Many of the target physics areas described in the Laser-Direct-Drive Research section are common to Laser-Indirect-Drive Research; however, there are important distinctions related to radiation hydrodynamics of the hohlraum (Lindl, 1998; Barrios et al., 2018; Callahan et al., 2018, 2020; Tikhonchuk, 2021), laser plasma interactions within the hohlraum (Glenzer et al., 2010; Kritcher et al., 2018; Callahan et al., 2020; Tikhonchuk, 2021), conversion of laser energy to shell kinetic energy (Lindl, 1998; Tikhonchuk, 2021), and the seeds of hydrodynamic instabilities (Barrios et al. 2013; Nagel et al., 2015; MacPhee et al., 2017; Martinez et al., 2017; Hammel et al., 2016, 2018; Tikhonchuk, 2021).

Two of the main design considerations for the hohlraum radiation hydrodynamics are the expansion of the high-Z ablation plasma into the hohlraum and the plasma conditions in the laser entrance hole region of the hohlraum, which can adversely affect the laser to x-ray energy coupling and the implosion symmetry (Glenzer et al., 2010; Barrios et al., 2018; Kritcher et al., 2018; Callahan et al., 2018, 2020; Tikhonchuk, 2021). The hohlraum is filled with a low-Z gas, which is ionized by the lasers forming a plasma that tamps the expansion of the high-Z ablation plasma. Target design considerations are made to optimize the energy coupling and implosion symmetry, while mitigating the laser plasma interactions in the hohlraum. Because of the area ratio of the capsule to the inner wall of the hohlraum, approximately 10% of the laser energy is converted to X rays in a hohlraum that are incident on the implosion capsule. The X rays deposit their energy close to the ablation surface of the implosion capsule, which increases the hydrodynamic efficiency of converting the absorbed X-ray energy to inward kinetic energy of the shell via the rocket effect to about 15% versus 9% for laser direct drive. This gives a conversion efficiency of laser energy to shell kinetic energy of about 1.5% for laser indirect drive versus 6% for laser direct drive. Consequently, laser indirect drive solves the laser imprint problem at a cost of lowering the conversion efficiency of laser energy to shell kinetic energy. Initiatives to increase the energy coupling to the capsule are explored using innovative hohlraum designs (Amendt et al., 2019) and increasing the size of the capsule, while keeping the size of the hohlraum fixed (Callahan et al., 2018, 2020). However, these initiatives will only lead to a modest increase in the energy coupling.

Over the last decade the primary neutron yield for laser indirect drive implosions on the National Ignition Facility has been increased from 2×10^{14} to 2×10^{16} (Moses et al., 2009; Glenzer et al., 2010; Meezan et al., 2010, 2015; Michel et al., 2010; Haan et al., 2011; Edwards et al., 2011, 2013; Landen et al., 2011, 2021; Hurricane et al., 2014; Le Pape et al., 2018, Hurricane et al., 2019a, b, 2021; Landen et al., 2020; Patel et al., 2020; Town, 2020; Zylstra et al., 2021). After an initial series of implosions on the National Ignition Facility, where the DT fuel was diluted with hydrogen (H) to reduce the yield (i.e., THD implosions), low-adiabat ignition designs having predicted yields around 3.6×10^{17} or greater than 1 MJ of fusion yield were explored (Haan et al., 2011). When the high neutron yields were not realized in the laboratory, a more phased approach using higher-adiabat implosion designs was undertaken to understand the implosion results (Hurricane et al., 2014). Using the higher-adiabat implosion, that is less susceptible to hydrodynamic instabilities, driven with a low-fill density hohlraums, that have lower levels of laser plasma interactions, alpha heating was demonstrated and burning plasma is now being explored on the National Ignition Facility with laser indirect drive. The highest yield published to date corresponds to 56 kJ of thermonuclear fusion energy, where alpha heating has boosted the fusion yield by a factor of three from that caused by the implosion system alone (Town, 2020; Patel et al., 2020). The generalized Lawson ignition parameter for laser indirect drive implosions on the National Ignition Facility is 0.75 (Patel et al., 2020).

The current hypothesis is the performance of the current laser indirect drive implosions on the National Ignition Facility is limited by the low amount of energy coupled to the hot-spot plasma and two physical degradation mechanisms (Town, 2020). The mode-1 asymmetry caused by the laser imbalance or capsule nonuniformities (Rinderknecht et al., 2020; Casey et al., 2021) and hydrodynamic instabilities seeded by engineering features such as the fill tube (Hammel et al., 2011; Regan et al., 2013; Ma et al., 2013; Pak et al., 2020), capsule support (Nagel et al., 2015; MacPhee et al., 2017; Hammel et al., 2016, 2018; Martinez et al., 2017), and capsule imperfections (Barrios et al., 2013; Town, 2020). This hypothesis is based on the current understanding of experimental results and modeling of alpha heating (Zylstra and Hurricane, 2019; Patel et al., 2020), hohlraum performance (Hall et al., 2017; Kritcher et al., 2018; Callahan et al., 2018, 2020), laser plasma interactions (Kruer, 2003; Regan et al., 2010; Glenzer et al., 2010; Dewald et al., 2016; Kritcher et al., 2018; Callahan et al., 2018; Callahan et al., 2020; Tikhonchuk, 2021), low-mode asymmetry (Kritcher et al., 2014, 2018; Rinderknecht et al., 2020; Casey et al., 2021), engineering feature such as fill tubes, capsule support, capsule quality (Martinez et al., 2017), and the quality of the DT cryogenic fuel layer (Gibson et al., 2009; Johal et al., 2009), low compression (Landen et al., 2020, 2021), implosion reproducibility (Town, 2020).

The thrust of the research over the next five years for laser indirect drive on the National Ignition Facility will concentrate on the following: (1) increasing amount of laser energy coupled to the implosion capsule (Amendt et al., 2019); (2) optimizing implosion symmetry (Callahan et al., 2018; Callahan et al., 2020); (3) mitigating hydrodynamic mixing of material into the hot-spot plasma; (4) increasing the convergence ratio of the implosion and the compressed fuel density (Landen et al., 2020, 2021); (5) improving predictive capability of implosion performance (Marinak et al., 2001; Clark et al., 2011, 2017, 2019a, b; Callahan et al., 2018, 2020; Gaffney et al., 2018, 2019); (6) increasing the energy and power of the National Ignition Facility (Town, 2020).

Ignition is a grand research challenge. Estimates for the amount of laser energy needed on the National Ignition Facility path forward to ignition with laser indirect drive on the National Ignition Facility range from 1.5 times the current 2 MJ of available laser

energy, if lower-adiabat implosion with higher energy coupling are viable, to 10 times the current 2 MJ of available laser energy, if no improvements are made to the current implosions (Town, 2020). Understanding the science and improvements in target fabrication with systematic experiments over the next several years will reduce the uncertainty in required driver energy and increase the fusion performance at the National Ignition Facility. Although incremental improvements to the performance are ongoing, understanding predictable ignition is crucial for the laser-driven inertial confinement fusion research.

Introduction

The idea of using accelerators for inertial fusion energy (IFE) was born during the “energy crisis” of the mid-1970s. The enthusiasm in the accelerator community was due in part to the fact that particle accelerators had been built for decades producing ever increasing particle energy and beam current. Many were reliable facilities generating high intensity beams, running nearly non-stop for weeks or months for nuclear and particle physics research and a growing number of industrial applications. Megajoules of beam energy (ion kinetic energy $\times$ number of particles in the beam), and terawatts of beam power had been demonstrated for high-energy physics and nuclear physics research. The ability to steer and focus such beams to sub-mm spots was well established.

As described in earlier chapters covering inertial fusion energy or inertial confinement fusion, the energy to compress and heat the fusion fuel is delivered with high intensity laser beams, ion beams or X-rays. While many of the first IFE experiments used lasers, the prospects for accelerator driven IFE gained momentum. High-level reviews of the US inertial fusion program through the 1990s concluded that accelerators were the most promising long-term approach (NRC, 1986, 1990; FPAC, 1990; FEAC, 1994; Sheffield et al., 1996). Ion driven inertial fusion is particularly compatible with the protection of the structural wall with neutron-absorbing, thick flowing liquid. In contrast to laser IFE, the final optical elements (electromagnets) can be straightforwardly shielded from line-of-sight irradiation and debris from the target.

In 1994 the US Department of Energy decided to build the National Ignition Facility (NIF), a laser-based facility designed to evaluate the feasibility of inertial fusion in the laboratory and as a testbed for nuclear weapons topics. Completed in 2009, a campaign of integrated ignition experiments began in 2010. The 2 MJ laser system has performed as designed, operating very reliably and has led to an evolution in the understanding of target physics. The results have pointed to issues that have, to date, impeded the demonstration of ignition at NIF. Nevertheless, as discussed by Regan (2021), there are reasons for optimism for ignition at NIF.

In 2003, the Department of Energy decided to de-emphasize IFE research, including heavy ion research, pending the demonstration of ignition on the NIF. But it continued accelerator research to study high energy density physics (HEDP) and warm dense matter physics (WDMP). This means creating, for a short time, states of matter exceeding temperatures of 10^4 K and pressures above the GPa range. This intersection of plasma and condensed matter physics is of interest for the study of giant planets, and stellar interiors. Also, as inertial fusion fuel is heated it passes through this regime.

This article aims to show the experimental progress supporting the heavy ion fusion (HIF) approach to inertial fusion energy, and is an introduction to the more detailed descriptions in the references. Bangerter et al. (2013) and Hofmann (2018) are recent reviews of HIF aimed at accelerator experts, including target physics and specific designs which in turn set the accelerator requirements. More experimental results than described here have helped develop HIF to the present promising status.

Target physics for HIF

The physics of compressing and igniting inertial fusion targets is described by Atzeni (2021), Tikhonchuk (2021) and Bangerter et al. (2013). Since different drivers (lasers, pinches, heavy ions) might have particular considerations, we briefly summarize the important issues and put heavy ion targets in perspective.

As for all IFE targets, it is necessary to trap the energy of the fusion reaction products in the fuel to assist with ignition and burn. This sets a lower limit on the size of the target (the fuel capsule radius is around 2 mm), and therefore the energy required to compress and ignite the target should be above roughly 1 MJ, deposited in ~ 10 ns. Target designs call for multiple beams, partly to compress the fuel uniformly, and also because it is very difficult to produce the required total beam power without multiple beams. Energetic ions are rapidly stripped of their electrons, greatly increasing their stopping power. Heavier elements have a shorter range at a given kinetic energy (Fig. 1). The suitable range for HIF targets is between 0.03 and 3 g/cm². Which ions and what beam current should be used? Maschke (1975) proposed that beams of heavy ions with a kinetic energy of several GeV would minimize the required beam current while meeting the desired ion range for the target dimension noted above. (Low kinetic energy—e.g., 20 MeV—protons have an appropriate range but the required beam current leads to greater problems with the ability to focus the beam.) A repetition rate of ~ 10 Hz is required to generate enough fusion energy yield to generate 1 GW of electrical power, a common output for an electrical power plant. Target, driver, and reactor designs can also be adapted for lower or higher electrical power in response to evolving electric grid paradigms.

HIF targets may be characterized by the implosion mode and the ignition mode. Direct drive and indirect drive are implosion modes, each with advantages and disadvantages. Direct drive targets, in which the ions penetrate the outer layer of the fuel capsule, ablate the fuel to produce high pressure to compress the fuel. This approach can be two to three times more efficient in the transfer of beam energy to the imploding fusion fuel than indirect drive targets. However, the tolerances on positioning and beam spot smoothness are more demanding.

For indirect drive targets, the beam heats a material inside a high-atomic-number hohlraum or cavity, which in turn produces radiation which heats the ablator material on the fuel capsule at the center of the hohlraum cavity. This transfer of energy has an energy penalty, and indirect drive targets will require a correspondingly higher total beam energy to compress and ignite a similar fusion pellet than direct drive targets. For indirect drive IFE targets the physics of the capsule implosion is the same for HIF targets and laser IFE targets, an important synergism with the NIF ignition. Indirectly driven targets might be more complex to fabricate than direct drive targets, consisting of various materials precisely located in the hohlraum to achieve uniform implosion of the fuel pellet. On the other hand, direct-drive fuel capsules likely require more stringent smoothness, and must survive the trajectory to the center of the chamber.

For direct drive targets the beam energy must be delivered in a time close to the implosion time, while for indirect drive targets, the beam energy is deposited in a time longer than the capsule implosion time. Some of the challenges in NIF experiments are in the implosion stage. Possible reasons include asymmetry in the drive pulses, interactions between the laser and the created plasma in the target when individual lasers cross (laser-plasma interaction), and asymmetries in the target-hohlraum geometry. Not all of these (e.g., laser-plasma interactions) are germane to HIF targets.

The most commonly considered ignition mode is fast ignition, shock ignition and hot-spot ignition. In fast ignition, a separate beam pulse from the implosion beams ignites a fraction of the target. In shock ignition, a high-power beam pulse creates a shock wave to help ignite the fuel. In hot spot ignition, the compression beams themselves heat and ignite part of the compressed fuel. Indirect drive, hot-spot ignition is the approach most explored at the NIF.

Fig. 1 Range as a function of kinetic energy in aluminum (at a temperature of 300 eV) for a variety of ions. From Bangerter RO, Faltens A and Seidl PA (2013) *Accelerators for Inertial Fusion Energy Production, Reviews of Accelerator Science and Technology*. vol. 6, pp. 85–116, World Scientific Publishing Company. <https://doi.org/10.1142/S1793626813300053>.

The choice of implosion and ignition modes leads to various trade-offs between target gain (ratio of the fusion energy yield to total beam energy), required beam energy, power, and focal spot radius. Detailed simulations of the target physics for particular designs have been carried out. In Bangerter et al. (2013), several designs are summarized, varying in beam energy between 3.5 MJ and 6.7 MJ, peak beam power from 470 TW to 30,000 TW, focal spot radius from 0.26 mm to 4.5 mm, ion kinetic energy from 3.5 GeV to 20 GeV and fusion gain from 60 to 300. These beam requirements span a wide range in fusion gain with implications for the accelerator requirements. The most demanding beam requirements are for fast ignition, and the more relaxed requirements are for hot spot ignition. To decide among these target design and accelerator combinations, an encompassing evaluation of the engineering challenges, reliability and economics of the whole system is required: accelerator, fusion reactor chamber, target fabrication and balance of plant. These system studies are discussed in the accompanying chapter by Dunne (2020).

Target requirements establish the ion beam and accelerator specifications

To illustrate how the target design is coupled to the accelerator requirements, we use a specific example, the close-coupled target (Callahan-Miller and Tabak, 2000), summarized in Table 1. This target design is attractive because it has a relatively high fusion gain and low beam energy for an indirect drive target and, relative to some other targets, moderate peak power requirements. The focal radius of 1.7 mm is somewhat demanding, putting it in the realm of requirements for some direct drive target designs.

We first examine two effects which limit the minimum focal radius. (Limitations due to chromatic aberrations in the lenses will be discussed later.) One is the electrostatic repulsion among the ions, or the space charge effect. The other is the spread of ion coordinates in position and momentum space transverse to the beam direction, which may be characterized by the beam phase space density, brightness, and emittance (Reiser, 2008).

Unnormalized brightness and emittance are related via the beam current, I :

$$B = I / (\epsilon_x \epsilon_y \epsilon_z) \quad (1)$$

Where ϵ_x and ϵ_y are the emittance in the two directions orthogonal to the direction of propagation (z). From Liouville's theorem we know that for a system under conservative forces, the six-dimensional phase space density is conserved. The six dimensional phase space density is proportional to the normalized brightness $B_n = B / (\gamma\beta)^3$, where γ and β are the usual relativistic factors. This means that in an accelerator with ideal focusing systems the density is conserved, while imperfections in the accelerator components (e.g., focusing lens aberrations) lead to an increase in emittance (by engulfing empty phase space) and sometimes particle loss. As we will see, both emittance and space charge place important performance constraints on the accelerator system.

From Table 1 we deduce that the number of ions per pulse is $3.5 \times 10^6 \text{ J} / 3.5 \times 10^9 \text{ eV} = 1 \text{ mC}/e = 6 \times 10^{15}$, and the peak current is $I_{\text{peak}} = 134 \text{ kA}$. These are unusually high values for any ion accelerator. These demanding values must be achieved at the target, while for much of the accelerator before the final beam compression (power amplification) and focusing, the radius and beam power may be relaxed.

To further discuss the roles of the beam space charge and brightness, we will separate the accelerator into three main parts: The ion source, the main accelerator, and the final focusing system. Ions are created in the ion source at low kinetic energy (0.1–2 MeV). In the main accelerator the ions are accelerated to the final kinetic energy and then compressed to a higher density, principally in the longitudinal direction, by compressing the bunches or “stacking” a series of bunches in, for example, an accumulator ring. In the final focusing system the beam is focused radially to meet the desired spot size at the target.

Because the driver must accelerate ions to the GeV range and the maximum acceleration gradient is 1–10 MeV/m for most of the accelerator (with the upper range being speculative at this point), most driver designs call for accelerators at least a kilometer in length. Since the accelerator is a narrow and long structure, the area occupied by the driver is still competitive with large baseload electrical power plants. Note that there can be a trade-off between beam current and ion energy to meet a fusion target power requirement. Lower kinetic energy implies a shorter accelerator, but more challenging space charge repulsion. Circular accelerators, where the beam passes through a small number of acceleration stations many times, would be attractive by reducing the overall length. They also have special beam physics considerations as we will discuss below.

Ion sources

The need for reproducibility at the fusion target means that the ion source should produce nearly identical pulses as characterized by the initial current, energy, size and convergence or divergence angles. Sources usually extract ions from a spark, plasma or a hot

Table 1 Beam parameters for the close coupled target, an indirect-drive, hot spot ignition target.

Energy (MJ)	Peak power (TW)	Focal radius (mm)	Gain	Ion	Kinetic energy (GeV)
3.5	470	1.7	130	Pb	3.5

From Bangerter RO, Faltens A and Seidl PA (2013) *Accelerators for Inertial Fusion Energy Production, Reviews of Accelerator Science and Technology*. vol. 6, pp. 85–116, World Scientific Publishing Company. <https://doi.org/10.1142/S1793626813300053>.

surface (surface or contact ionization). The ions are then accelerated across one or a handful of high-voltage gaps to 10's of keV to the MeV range (Brown, 2004). It appears to be necessary to operate in the space-charge limited mode, so that the variations in beam current that would otherwise be caused by the fluctuations in the ionization process are eliminated. Thus, the emission current density (or ionization rate) should be greater than the space charge current density by some margin to accommodate emission fluctuations. The Child-Langmuir formula for space charge limited flow in a planar gap (gap distance, d) shows the dependence of the ion current density (J) on the geometry and voltage (V) across the gap.

$$J_{CL} = (4\epsilon_0/9) (2qe/M)^{1/2} V^{3/2} / d^2 \quad (2)$$

where J is the current density, ϵ_0 is the permittivity of free space and M is the ion mass. In order to maximize the current density and the current ($I = J \bullet a^2$, where a is the source beam radius), the source should operate at the highest voltage allowed by high-voltage breakdown considerations while still delivering space-charge limited flow. The formula also shows that the voltage must be very stable to prevent unwanted current variations.

Various effects contribute to the phase space volume occupied by the beam. The ions are created or born with a spread of momenta which may be approximated by a temperature (though the distribution may not be Maxwellian). The associated rms velocity per degree of freedom is $v = (T/M)^{1/2}$ where T and M are the temperature and mass in eV and eV/c², respectively. One can then define the normalized transverse emittance, ϵ_n , and relate it to the rms velocity (for a beam not undergoing expansion):

$$\epsilon_n \equiv a\beta\gamma\theta = 2a(T/M)^{1/2} \quad (3)$$

where a is the beam radius. For most heavy ion fusion drivers the final ion energy is mildly relativistic, so $\gamma \approx 1$. θ is the beam spread or divergence angle. The non-relativistic beam velocity allows for manipulation of the beam current by modulating the velocity of different parts of the pulse. More generally for an expanding beam, $\epsilon_n = \beta\gamma\epsilon_x \equiv 4\beta\gamma(\langle x^2 \rangle \langle x'^2 \rangle - \langle xx' \rangle)^{1/2}$, where the derivatives are with respect to the direction of beam motion (z) and the brackets indicate rms quantities of the ensemble of particles.

The longitudinal phase space volume or emittance is often expressed as the product of the pulse duration (t , in seconds) and the energy spread, ΔE , in eV. If the particles have a longitudinal velocity spread v in the beam frame of reference, then in the laboratory frame the velocity is $v_0 \pm v$ and the energy spread ($2\bullet$ rms) in the laboratory frame is $\Delta E = 2Mv_0v$. If the velocity spread is due to the aforementioned source temperature, T , then the longitudinal emittance, ϵ_L , is:

$$\epsilon_L = (2ET)^{1/2} t \quad (4)$$

One can see from the expressions for ϵ_L and ϵ_n and their dependence on T and E that, in addition to the ion temperature at the point the ions are formed, rapid fluctuations in the extraction voltage during the pulse will also contribute to the emittance. Another source of emittance increase is imperfection in the ion extraction and acceleration fields.

The maximum high voltage against breakdown in the vacuum system varies as $d^{1/2}$ for $d > 1$ cm and linearly with d for $d < 1$ cm (Kwan, 2005), and for extraction optics with low aberrations $a \leq d$ should be satisfied. It follows that the six-dimensional phase space density, or beam brightness,

$$B = 1/(\epsilon_L \epsilon_n^2) \quad (5)$$

increases with decreasing a or d . Thus, small radius beams with short extraction gaps are brighter, but will also have lower current, which must be reconciled with the current requirement set by the target design and final ion kinetic energy. The lower current can be compensated by configuring the source with many smaller, higher-brightness beams which are very closely spaced, and merged into a single beam after extraction. The empty space between beams means that the average brightness of the merged beam will be lowered somewhat than that of the individual beams, but is still attractive.

It is tempting to design sources to create higher charge state ions ($q > 1$) because the ions can be brought to the final kinetic energy in the accelerator in a shorter distance. For example, a factor of two, for $q = 2$ vs. $q = 1$ could be attractive economically. Note that the current density (Eq. 2) increases as $q^{1/2}$, while the particle current (or number density) of the beam decreases inversely with q for a given current, thus decreasing brightness. Since space charge is especially challenging at low kinetic energy, an alternative is to start with $q = 1$ ions and strip the ions to a higher charge state at an intermediate kinetic energy. One difficult trade-off is that the stripping process leads to a distribution of charge states and a lower brightness, since only one charge state is utilized. To date, the brightest sources for HIF tend to be $q = 1$ plasma sources or aluminosilicate (surface ionization) sources.

For induction accelerator drivers, several candidate sources for HIF are summarized by Kwan (2005). Surface ionization sources have generated MeV and ampere-level beams (Bieniossek et al., 2005) as illustrated in Fig. 2. Beams formed from the merging of many, small radius beams with a total current of ≈ 0.5 A are also promising, based on experiments and simulations. The current/beam for RF drivers is usually lower, and suitable high brightness beams with 40 mA current have been demonstrated (Hofmann and Plass, 1998; Ratzinger, 2001). The CHORDIS ion source is filament driven with a small plasma chamber and a permanent magnet array to maintain a high plasma density.

The goal of developing laser-driven ion beams with high efficiency and low energy spread has been advancing in the past decade. For example, intense lasers (few ns, $\sim 10^9$ W/cm²) produce ions in an expanding plasma plume after striking a solid target. Extraction of these ions into a longer, low emittance bunch has been proposed for HIF ion sources and injectors (Okamura, 2018), where the production of low charge state ions has been demonstrated. Remaining challenges include the time variation of the beam during the 20–50 μ s extracted pulse and clearing unwanted charge states.

Fig. 2 Beam footprint from a prototype ion source and injector for heavy ion fusion (Bieniosek, et al., 2005). At 2 MeV, the injector generates a 5 μ s, 0.8 A pulse. From Bieniosek FM, Celata CM, Henestroza E, Kwan JW, Prost L et al. (2005) 2-MV electrostatic quadrupole injector for heavy-ion fusion. *Physical Review Accelerators and Beams* 8: 010101. <https://doi.org/10.1103/PhysRevSTAB.8.010101>.

Main accelerator

High energy accelerators generate beams of charged particles by acceleration due to electric fields, while the beams are focused with magnetic or electric lenses. Magnetic quadrupole lenses, arranged in an alternating gradient pattern are particularly common in particle accelerators. The fields in the horizontal plane switch from focusing to defocusing in each successive quadrupole. The focusing is reversed in the vertical direction. This pattern repeats with a period $2L$, where L is the distance between successive quadrupoles. The acceleration fields are typically generated between electrodes in a gap between quadrupoles. These accelerating gaps are realized with either RF cavities (RF accelerators), or from high-voltage pulses (e.g., induction accelerators). We will first discuss the focusing of the beam in the accelerator.

Ion-driven fast ignition requires shorter pulses of high brightness beams, with a pulse energy of ≈ 100 kJ to a few MJ (Henestroza and Logan, 2012) and meeting the stringent requirements of rapid and highly localized target heating is a more difficult challenge due to chromatic and other aberrations (Bangerter et al., 2013). Laser driven ion beams can produce 10 MeV to 100 MeV ions within a small transverse radius. This method has been studied for the heating of matter to high temperatures for HEDP and for ion-driven fast ignition (Fernandez, et al., 2014), where the laser pulse would create the ion pulse very near the target without the need for post acceleration. In this case recent results have shown an improved overall efficiency and reduced energy spread. The lasers themselves can be about 20% efficient (wall plug to photons), with efficiencies up to 50% envisioned (Hooker, 2013). An efficiency of energy transfer from the laser pulse to the ions of 5% has been demonstrated (Palaniyappan et al., 2015). Higher brightness and efficiency are needed and might come into reach with laser technology advances and demonstrations of advanced laser-ion acceleration mechanisms (Park et al., 2019).

Space charge, transverse emittance and transportable current

Though space charge is usually the limiting factor on transportable current in the main accelerator, the emittance must also be kept low enough to meet the focusing requirements at the target. This is non-trivial; it has to stay low over many focusing elements in an accelerator where the beam path length may be several kilometers and where deleterious effects will accumulate, lowering brightness. Driver designers routinely stipulate that the brightness at the ion sources should be greater than that required at the target by a substantial margin to accommodate these real-world effects.

The contributions from the transverse emittance and space charge can be seen with the beam envelope equation, which describes the evolution of the transverse shape of the beam through the focusing lenses (quadrupoles):

$$\frac{d^2a}{ds^2} = \pm k_x^2 a + \frac{2Q}{a+b} + \frac{\epsilon^2}{a^3} \quad (6)$$

The equilibrium beam shape is elliptical, where a and b are the semi-minor and semi-major beam radii. k_x^2 contains the focusing effect from the quadrupoles—its sign depends on whether the quadrupole is focusing or defocusing along the a axis. A similar equation describes motion in the orthogonal (b) direction. The perveance is $Q = I_a q e / (2\pi\epsilon_0 M c^3 \beta^3 \gamma^3)$, a dimensionless quantity, representing the defocusing of the beam due to its electric and magnetic fields. The transverse emittance, ϵ , is assumed here to be equal in both transverse planes.

The focusing term can be related to an important characteristic of accelerator focusing systems, the phase advance. Individual particles oscillate with characteristic periods in focusing systems with repeating structures. In an alternating gradient quadrupole channel, a single charged particle's phase advances by σ_0 per full lattice period ($2L$) and

$$k_x = \frac{\sigma_0}{2L} \quad (7)$$

σ_0 is referred to as the single-particle phase advance, which characterizes the oscillations in the case of low space charge or current. Higher strength quadrupole magnets correspond to higher σ_0 . Due to the onset of instabilities there is a limit on the phase advance at and above $\pi/2$, and practical accelerator designs tend to keep the phase advance to $\leq 85^\circ$.

Increasing perveance (beam current or space charge) depresses the particle phase advance to lower values. Since unusually high current beams are needed for HIF, an important early question concerned the lower limiting value of the ratio σ/σ_0 , or tune depression, that could be realized without beam instabilities or other problems. This was answered by experiments with simulations of high perveance and low kinetic energy ion beams which showed that $\sigma/\sigma_0 \approx 0.1$ is possible for $\sigma_0 = 85^\circ$ (Tiefenback and Keefe, 1985; Tiefenback, 1986). In a later experiment near driver scale (1 MeV, 0.2 A), a K^+ beam injected into a quadrupole channel showed no emittance growth while $\sigma/\sigma_0 < 0.2$ (Prost et al., 2005).

The space charge repulsion of the beam must also (in addition to the defocusing due to emittance) be balanced by the electromagnetic focusing elements (electromagnets, e.g., quadrupoles, or electrostatic equivalents). For a fixed focusing strength, a beam with higher space charge repulsion (higher beam current) will have a larger equilibrium radius and, with further increase of space charge, some particles will graze the beam pipe and be lost.

The fundamental limit on the transportable beam current in an accelerator focusing system is referred to as the Maschke limit (Maschke, 1979). Maschke proposed to set the maximum transportable current such that the space charge forces were one-half the average focusing forces. Here we give the maximum transportable current for a series of magnetic quadrupoles. Assuming that the quadrupoles occupy one-half of the beamline, respecting the known limits of beam stability, and for an average beam radius one-half the bore radius ($a/b = 0.5$), the maximum transportable current is (Bangerter et al., 2013):

$$I < 5 \times 10^5 * B_b * \beta^2 \gamma^2 a \quad (\text{Amperes}) \quad (8)$$

where B_b is the magnetic field in Tesla at a distance b (in meters) from the axis (the beam pipe radius). This expression is approximately the same as the Maschke limit. Similar expressions may be derived for solenoid lenses or electrostatic quadrupoles. $B_b = 5$ T is representational of a modern superconducting quadrupole. For the beam parameters in Table 1, and taking as an example $a = 0.03$ m, the Maschke limit is 2.8 kA, small compared to the total beam current of 134 kA. This is a practical reason to distribute the total current into many lower current beams. Eq. (8) shows that for a practical limit on the peak magnetic field, the transportable current increases with the particle velocity in magnetic quadrupoles.

Superconducting coils (vs. normal conducting coils) are essential for overall electrical efficiency of the driver. The technology is advancing, with numerous research groups pursuing the development of higher focusing strength to match the strong interest in higher kinetic energy and higher intensity accelerators for high-energy and nuclear physics research. This kind of synergistic research is of high value. Earlier generations of superconducting quadrupoles used NbTi conductors, but have been superseded by higher current density Nb₃Sn conductors (Schoerling and Zlobin, 2019). Pursuit of higher fields from high-temperature superconductors such as BSSCO (Bi-221) and rare earth barium copper oxides (REBCO) is becoming more common (Wang et al., 2021).

The loss of particles is of concern in accelerators because of the decrease in beam power, and the possible radioactive activation of accelerator components. For a fixed physical aperture, the fractional loss increases with the increase in the rms beam size. Prost et al. (2005) showed no particle loss while the beam filled 60–80% of the clear aperture. Particle loss is also caused by field imperfections and misalignments distorting the distribution and causing the beam centroid to wobble about the primary axis. The lost particles also cause the desorption of electrons, ions, atoms and molecules from the vacuum chamber wall leading to a transient increase in pressure (Cohen et al., 2005). In circular accelerators, particle loss is a particular concern which can lead to a beam-destroying runaway situation: the pressure can build up with successive laps of the beam bunch around the machine leading to beam-gas collisions and further beam loss. This has been addressed in experiments and will be discussed below.

Radiofrequency accelerators

Radiofrequency (RF) accelerators, invented almost a century ago, are a mature technology with a large international research community continuing to push the performance to higher energy and beam intensity. RF accelerators add energy to particles through a series of voltage steps where the fields in the acceleration gap are driven by an RF source (e.g., a klystron). The driven load is often a high-impedance and high-Q resonant cavity connected to the acceleration electrodes and therefore high fields can be established in the acceleration gap. In the case of cyclic accelerators there are no more than a few acceleration gaps in the ring and very high kinetic energy can be achieved by many circulations of the charged particle bunch. In an RF linear accelerator there are typically many gaps to attain the desired ion kinetic energy, and particles pass through each gap only once. Since many gaps in the accelerator are driven by a common RF frequency, the charged particles must arrive during the accelerating part of the wave at nearly the same phase. The particles tend to reside in a bunch around this synchronous phase. The phase window in which the particles reside and are stably accelerated through many acceleration gaps is referred to as the RF bucket. Thus, the spacing between successive gaps must be $n\beta\lambda/2$, where n is an odd integer and λ is the wavelength of the RF field. There is a tendency for longitudinal spreading (defocusing) of

the bunch due to space charge and emittance. This is counteracted by locating the bunch on the negative slope of the RF wave. In the transverse plane the beam is confined by magnetic quadrupoles between the acceleration gaps.

Since the acceleration gaps in a cyclic accelerator are traversed many times by each particle, the acceleration volts are relatively inexpensive compared to a linear accelerator. Synchrotrons are a type of cyclic RF accelerator where the guiding magnetic field is varied to match the increasing momentum of the accelerated particles. They have generated some of the highest kinetic energy ions and electrons and are the basis for state-of-the-art facilities for high-energy physics research. The Large Hadron Collider at CERN is an iconic example (Llewellyn Smith, 2015). Acceleration of ions with synchrotrons followed by the accumulation of charge in storage rings (a particular type of synchrotron where the kinetic energy is kept constant) were among the first HIF driver concepts in the 1970s and 1980s. There are some important hurdles with synchrotrons for HIF. More detailed and sophisticated target designs showed that the desired ion range was lower than originally anticipated, corresponding to lower ion kinetic energy (and higher beam current, which is more challenging in cyclic accelerators). Furthermore, there is great sensitivity in a synchrotron to collisions among the ions and with the background gas molecules, since the beam must circulate repeatedly while stray ions striking the accelerator wall desorb neutral particles. Recently this has become an urgent problem to be solved for the Facility for Antiproton and Ion Research (FAIR), a high-intensity heavy-ion synchrotron in Germany. Experiments and simulations are guiding the development techniques to trap desorbed particles within the accelerator. These are promising developments for storage rings in HIF drivers (Spiller and Barth, 2014).

Following the earlier synchrotron approach, RF linear accelerators in combination (usually) with storage rings have become the preferred design choice for the RF approach. An important advantage of the linear accelerator (LINAC) is that it allows for higher current per beam bunch compared to a synchrotron. Also, the preservation of brightness is much less sensitive to collisions with background gas molecules, since it is a single-pass structure with ample time between driver pulses (~ 100 ms). Since the spacing between RF acceleration stations increases in proportion to the particle velocity, with increasing velocity the spacing becomes sparse and the average acceleration rate per unit length decreases. Therefore, it is advantageous to occasionally double the RF frequency and to then accelerate with the more densely spaced bunches. This can be accomplished with parallel RF accelerators upstream (at the lower frequency). Beams from pairs of accelerators operating at the lower frequency fill stable phase intervals downstream of the transition, thereby occupying each period at the higher frequency. This funneling of bunches into a single beamline was experimentally demonstrated by Zimmermann et al. (2001) by deflecting beams from two parallel accelerators into a single beamline (Fig. 3).

Most of the acceleration occurs after funneling, in a single accelerator at a fixed RF frequency (~ 400 MHz). The peak current in the LINAC is on the order of 1 A, and is constant through the main accelerator, with an electrical (wall plug to beam) efficiency of about 25%. Once the ions reach the top kinetic energy the bunches are injected into a storage ring for current amplification. There the number of ions is accumulated to meet the fusion target specifications and extracted into a structure which compresses the beam longitudinally before focusing onto the target. Fig. 4 shows an RF driver layout from the European HIDIF (Heavy Ion Driven Inertial Fusion) study (Hofmann and Plass, 1998).

Induction accelerators

Induction linear accelerators were invented well after RF accelerators by Christofilos et al. (1963) to generate very high current pulses of energetic electrons for a fusion energy experiment. Since the kiloampere-level beam current exceeded what was (and is) possible with RF accelerators, it became the main approach developed for HIF in the United States. The acceleration field is generated by pulsed power to each acceleration station and, unlike the RF system described above, the modulator drives the beam directly. The pulsed power drives a low-impedance circuit comprised of cylindrically symmetric toroidal cells loaded with ferromagnetic material. An electric field appears across the gap in the bore of each cell, accelerating ions, and the process is repeated until the final kinetic energy is achieved. A toroidal hoop of ferromagnetic material limits the needed drive current over the pulse duration until

Fig. 3 Schematic of the RF funneling principle. Beams from pairs of accelerators operating at the lower frequency (f) fill stable phase intervals downstream of the transition, thereby occupying each period at the higher operating frequency ($2f$). Experiments showed the funneling of two beams into a single RF accelerator. Zimmermann H, Bartz U, Fieck D, Fischer P, Vossberg M et al. (2005) The frankfurt funneling experiment. In: *Proceedings of the 2005 Particle Accelerator Conference, Knoxville, TN, USA*. pp. 677–679, <https://doi.org/10.1109/PAC.2005.1590525>.

Fig. 4 The RF-accelerator based HIDIF driver design begins with 48 ion sources and low-frequency RF sections funneling into a main LINAC. At the end of the accelerator the beam is fed to multiple storage rings followed by an induction LINAC buncher. Hofmann I and Plass G (1998) The HIDIF Study: Report of the European Study Group on Heavy Ion Driven Inertial Fusion for the Period 1995–1998. GSI Report 98-06; <http://www-alt.gsi.de/documents/DOC-2009-Feb-44.html>

the saturation flux density is reached. Electrical efficiency of 50% (wall plug to beam power) has been demonstrated in high-current electron accelerators (Takayama and Briggs, 2011). The induction cell has low impedance and requires a very high (kA range) drive current to achieve the desired acceleration fields.

The voltage waveform may be customized at each station to accelerate and compress the beam pulse. This allows for current amplification during acceleration without the need for the additional beam manipulation of injection into a storage ring for current amplification. Thus, the ability to transport greater current for a practical limit on the magnetic field, B , (Eq. 8, a consequence of the Lorentz force) allows for current amplification to keep pace with the transportable current in the quadrupoles. Between successive acceleration cells, quadrupoles keep the beam transversely confined against the defocusing from space charge and emittance. The timing of the pulsed power is adjusted to match the arrival time of the beam, and so the placement of successive cells is chosen to keep the spacing between cells compact while the kinetic energy increases. The high beam current creates a longitudinal self-field which is greatest at the ends of the bunch, pushing particles away from the center of mass of the moving bunch. This is counteracted with specialized induction cells creating “ear” or “barrier” pulses to keep the pulse contained. The ear pulses counteract the longitudinal electrostatic field of the bunch, predominantly at the ends of the pulses.

Inspired by the potential cost savings of circular accelerators, a driver design based on a recirculating induction accelerator was developed, and a scaled experiment explored some of the beam physics issues (Ahle et al., 2001). Though the ring was only partially completed, the experiment demonstrated coordinated bending and acceleration of a space-charge dominated heavy-ion beam. Using a low energy beam of electrons, similar physics was explored at the University of Maryland Electron Ring, with induction acceleration cells, quadrupoles and dipoles. High brightness beams with 1000 turns of circulation were achieved (Kishek et al., 2014). A related experiment at a high-energy physics lab in Japan accelerated protons from 500 MeV to 6 GeV with repeated induction acceleration steps of 6.4 kV per turn in a ring with a circumference of 340 m. To counter the tendency of the beam to spread longitudinally, the beam was confined with barrier bucket pulses with a dedicated induction cell, where the barrier pulses applied a repulsive potential barrier to particles near the ends of the bunch.

Multiple, parallel beams in the accelerator

The high-current capability of induction accelerators led Maschke (1979) to suggest the acceleration of many closely spaced, parallel beams of ions with arrays of quadrupoles between acceleration cells. All the beams pass through common induction cells, a distinct

feature of induction linear accelerators for HIF compared to most induction accelerators (Fig. 5). The choice of multiple beams in the induction accelerator is driven in part by the need to focus to a small radius at the fusion target. As will be discussed later, focusing at the target is less challenging for lower current per beam. There is also a cost advantage: Consider a total current I_t distributed equally among N beams, with the quadrupoles nested compactly in a four-fold symmetric array. Averaged over the transverse dimensions of a multiple beam array within the bore of the induction cell, the array is more compact and leads to lower cost than a single beam of current I_t . This arises due to practical limits on the fields which can be generated in superconducting quadrupoles and on the focusing force required to counteract the dominant space charge term (Eq. 6). Arrays of tens to hundreds of beams are usually proposed. For greater values of N , the quadrupole size decreases, the fraction of space occupied by conductor, insulation and support structure leaves less space for the beams and the average beam current density of the N beams eventually drops. Also, practical alignment tolerances become more important as the channel size decreases. Motivated by the multi-beam approach, compact RF accelerator structures (mm-scale) which accelerate many parallel beams (Vinayakumar, et al., 2019) are in early development.

Induction accelerator designs usually start with initial beam pulses from the injector in the 1–30 μs range from many identical ion sources. Each beam is injected into individual channels of a multiple beam accelerator. The bunch compression continues until the bunch duration is 0.1–0.25 μs . This compression leads to a high beam current, where the electrical efficiency of the pulsed power and induction cells is high. The acceleration proceeds at a constant bunch duration until the final kinetic energy.

A disadvantage of induction accelerators is that the technology is less developed than RF accelerator technology. The main advantage of linear induction accelerators is in preserving beam brightness, since the beams keep their identity through the accelerator and to the target, and there are fewer beam manipulations than in RF designs. The induction accelerator approach would benefit from advances in lower-cost, long-life pulsed power, higher-gradient insulators, and robotic manufacturing of superconducting quadrupole arrays (Seidl et al., 2013).

Cost is a critical issue for the feasibility of fusion energy. Not surprisingly, the main accelerator is a major cost center of the overall driver. For RF designs the focusing quadrupoles, RF cavities, and RF power are important (Hofmann, 2018). The required peak power, from a few to 100 GW, is generated by gridded tubes or klystrons. For the highest peak power driver designs (fast ignition), the capital cost of the RF power is particularly challenging (Bangerter et al., 2013).

Superconducting RF cavities would lower the operating cost of the driver. For example, the Spallation Neutron Source accelerates 1.4 mA (average current) proton pulses with a 6% duty cycle, and 23 mA within the macro-pulses (Kim et al., 2017). Higher intensities are planned for future neutron sources (Garoby et al., 2018).

Beam compression

Compressing the beam in the direction of motion is essential because the beam current from the best ion sources is much less than that required by the target. RF LINACs are constant current devices, while induction LINACs can have varying current along the accelerator, leading to different beam compression approaches.

In the RF case the beam current remains constant from the source to the top kinetic energy of several GeV. Current amplification happens subsequently, as shown by the HIDIF example (Fig. 4). By using multiple ion species with the same momentum but slightly different velocity the beam compresses. The species are generated in separate ion sources and funneled into a common RF accelerator, as described above. The lighter ions have a higher velocity and catch up to the heavier species as the ions approach the fusion target, resulting in a “telescoping” effect, amplifying the beam current. Modeling, supported by the established energy acceptance of RF accelerators, suggest that three (Hofmann, 2018) species with a mass difference of a few percent accomplishes

Fig. 5 Schematic of an induction accelerator driver begins with multiple ion sources injected into separate focusing beamlines. All the beams are accelerated by common induction cells. After acceleration to the top kinetic energy the beams are compressed longitudinally. The last beam manipulation is the final focusing onto the fusion target. Bangerter RO, Faltens A and Seidl PA (2013) *Accelerators for Inertial Fusion Energy Production, Reviews of Accelerator Science and Technology*. vol. 6, pp. 85–116, World Scientific Publishing Company. <https://doi.org/10.1142/S1793626813300053>.

the goal. The telescoping of different species in a common RF accelerator has yet to be demonstrated. The species eventually overlap near the target, this leads to some issues yet to be tested by simulations or experiment—for example, that of the mutual space charge repulsion between bunches and whether associated brightness dilution is within limits.

Since the beam brightness decreases due to injection of the beam into, and extraction of the beam from, the storage rings, there has been some effort to design around this step. [Burke \(2014\)](#) proposed a driver with higher peak beam current in the main accelerator while telescoping six ion species (no storage rings, so “single-pass”). The design is based on a fast-ignition fusion target, which is part of the reason for higher peak current.

In the induction accelerator, the current increases during the acceleration by bunch compression. This is accomplished by applying acceleration waveforms with a small positive slope. Within the center of mass of the moving bunch, particles move inward and the bunch shortens, or compresses. As a result, the bunch current increases gradually as kinetic energy (E), increases, while staying below the transport limits in the quadrupoles.

Once ions have reached the final kinetic energy, the beam enters a drift section (only focusing quadrupoles) and the beam compresses further to the duration and pulse shape required at the target. This is accomplished via compression waveforms designed to compress the beam from ~ 100 ns to < 1 ns (fast ignition) to ~ 10 ns (indirect drive) as required by the particular target design. This penultimate beam manipulation is often referred to as drift compression. It is followed by the final focusing of the beam with lenses near the entrance of the target chamber. In drift compression, the minimum bunch duration is limited by the space-charge repulsion of the beam in the longitudinal direction. At this point, electrostatic repulsion has stagnated the inward longitudinal motion induced by the compression waveforms.

Experimental support for the simultaneous acceleration and compression of the beam comes from MBE-4 ([Fessenden, 1989; Fawley et al., 1997](#)). Four parallel space-charge-dominated beams were accelerated and compressed for a nine-fold increase in current in an induction accelerator using custom waveforms with 24 induction cells. Though emittance growth was observed during the compression, the causes of (and corrections for) the decrease in brightness were identified with detailed multi-particle simulations.

To compress beams having space charge forces too high to meet the target requirements, it is possible to mostly eliminate the repulsion of the beam by passing it through a plasma. The electron distribution of the plasma responds to the ion beam and effectively cancels out the space charge forces of the beam. The compression proceeds to the minimum bunch duration limited by the longitudinal emittance of the beam. Ion energy variation from the compression is still present at the target, contributing to greater chromatic aberrations in the final focusing to the fusion pellet.

Neutralized drift compression and focusing has been experimentally demonstrated in experiments NDCX-I ([Coleman et al., 2007](#)) and NDCX-II. In these studies, a plasma ignited near the surface of the drift tube filled the tube to a number density somewhat higher than the peak ion beam density, providing sufficient electrons to neutralize the space charge forces. The bunch duration and focal spot sizes after the final lenses were in good agreement with multi-particle beam and plasma simulations.

NDCX-II is a new ion induction accelerator for the study of rapid heating and radiation effects in materials from high-brightness ion beams ([Barnard et al., 2014](#)). Starting with ~ 1 μ s duration injected pulse, it simultaneously accelerates and compresses the beam to a few ns duration and mm-radius at the target, including neutralized drift compression and focusing ([Fig. 6](#)). The results confirm predictions from multi-particle simulations ([Seidl et al., 2017](#)).

Final focusing

The ion beam is accelerated with a much larger radius than the target focal radius. The beam is then compressed longitudinally, and then the final focusing lenses near the reactor chamber impart a convergence angle to the beam. The final focusing lenses have a focal length slightly greater than the standoff ($f \approx 10$ m) between the target and the reactor wall. The minimum focal spot radius will be limited by space charge and the emittance. To see how space charge limits the focal spot, briefly ignore the emittance term and integrate the envelope equation (Eq. 6). For a convergence angle θ_o , initial beam radius r_o , and radius at the target r_t :

$$\theta_o = (2Q \ln(r_t/r_o))^{1/2}$$

This can be rewritten in terms of a current limit using the definition for the perveance, and the degree to which the beam is neutralized by a factor $(1 - f_n)$, representing the difference between the density of the beam ions and the plasma electrons:

$$I_e < 8 \times 10^6 \left(\frac{A \beta^3 \gamma^3 \theta_o^2}{f_n q \ln(r_t/r_o)} \right) [\text{Amperes}],$$

where A is the ion mass in amu. If the degree of neutralization is high ($f_n \rightarrow 0$) then the spot will be limited by the emittance and chromatic aberrations, and other effects. The above result is important because it shows the effect of mass, ion charge state and ion velocity on the current per beam on target.

The target sets a lower limit on the brightness or six-dimensional phase space density. The limit on transverse momentum spread (part of the transverse emittance) is $r_t p / f$. This is the fraction of the beam momentum allowed in the transverse plane for a required r_t . In the transverse direction, the phase space volume is constrained by the fraction of the total solid angle available for focusing at the reactor wall. At the wall of the reactor chamber the transverse spatial area of the phase space volume is Ωf^2 , where Ω is the solid

Fig. 6 NDCX-II (LBNL) compresses and focuses ions in an induction accelerator to nanosecond bunches and millimeter focal spots. It uses many of the beam manipulations needed in an induction accelerator driver for fusion. The inset shows a 2 A beam focused to 2-mm FWHM.

angle occupied by all the beams. As discussed by [Dunne \(2021\)](#), in order to allow space for breeding tritium and for collecting the energy released by the fusion reactions, Ω is necessarily much less than 4π . Indirect drive targets with cylindrical symmetry typically call for two-sided illumination and the solid angle of the two groups of beams must be ≤ 0.5 . One must consider the packing of beams at the wall, and clearance required to accommodate beam halo and alignment tolerances. This clearance requirement reduces the solid angle occupied by all the beams to ≈ 0.1 .

The longitudinal phase space components are the energy spread and pulse duration. Usually the most important issue driven by energy spread is chromatic aberrations in the final focusing lenses, leading to a broadening of the focal spot compared to that of a monochromatic beam. For most driver designs these focusing elements are quadrupoles and the increase in the focal radius due to the chromatic effect ([Bangerter et al., 2013](#)) is approximately $\xi = \alpha \delta f \theta_0$, where δ is the fractional momentum spread of the beam, and α is a parameter dependent on the design of the focusing system. Thus, targets that require small focal spots (and small ξ) have stricter requirements on the momentum spread.

Several significant experiments have explored the issues above and have validated specific final focusing designs. They have been carried out at reduced kinetic energy and beam current. [MacLaren et al. \(2002\)](#) showed that the equations that governed the focusing of a driver beam when scaled down correctly gave the expected focal spot. The focusing design was based on a specific RF driver design for 10 GeV Bi^+ beams at 1.25 kA/beam. Several experiments have explored the neutralization of space charge for transverse focusing and drift compression. [Welch et al. \(2008\)](#) showed ion beam space charge neutralization with a background plasma,

greatly reducing the focal spot size compared to un-neutralized focusing. Simultaneous with the focusing, a significant bunching waveform was applied to the beam, compressing the beam longitudinally by a factor of > 60 in a few meters.

NDCX-II showed simultaneous drift compression and focusing in the presence of a neutralizing plasma. The beam is accelerated by 12 induction acceleration and compression cells, while transversely confined by 29 solenoid lenses before entering the background plasma of the drift compression and final focusing lenses. It is a significant test of the main beam manipulations of an induction linear accelerator driver for HIF (injection, acceleration, compression and focusing).

As implied above, the overall 6D brightness constraint is a minimum, but not sufficient condition. The beam must have the right shape at the target, typically longer in the direction of motion. The beam for an induction LINAC driver is considerably longer than it is wide and initially has a higher temperature in the transverse direction and will transfer energy to the longitudinal direction, up to some fraction of the former. In the case of RF drivers the bunches are shorter, but still greater in length than the transverse dimension. RF buckets contain ion bunches with duration typically < 1 ns, occupying a small fraction of the RF wave at, say, 200 MHz.

Summary and outlook

Nuclear and high energy physics accelerators with total beam energy of ≥ 1 MJ have separately exhibited efficiencies, pulse repetition rates (> 100 Hz), power levels, and durability required for IFE. The two principal approaches to heavy ion drivers are RF accelerators and induction accelerators. RF accelerators are appealing because of the extensive experience in high energy and nuclear physics; and induction accelerators, because of their much higher efficiency and higher particle beam current (≈ 10 kA). While recent results in from the laser-plasma acceleration of ions are encouraging and their application to advancing high energy density science, the application to IFE will require advancements in laser technology for efficient acceleration of high ion current.

The beam brightness and alignment must be such that the beam can be focused onto the target to a radius of a few millimeters from a distance of several meters. Limitations due to space charge, emittance growth, beam-gas, and beam-plasma interactions must be sufficiently controlled throughout the driver. Because of the high charge per bunch, the general approach is to accelerate a longer pulse and then compress it to the short length required at the target. The strategies for doing so differ depending on the main accelerator. Several of the experimental results were performed at reduced energy and current in such a way as to preserve the relative emittance and space charge effects expected in a driver. These experiments addressing main components of the driver are encouraging. **Table 2** summarizes a subset of the experimental results that test the HIF approach, including research not described above.

The opportunity to address remaining issues and to reduce risk in the development of HIF is timely given the progress at the NIF and advances in accelerator technology and computer modeling of intense beams and plasmas. Scaled experiments at heavy ion accelerators (e.g., Schoenberg et al., 2020) and with laser driven ion pulses can support the development of target designs and benchmarking simulation codes. Beam experiments to, for example, tackle remaining beam physics related to compression and focusing are possible with a modest research investment. Any future integrated experiment capable of testing beam physics at full scale, including heating, compressing and igniting targets will require the development of technology to reduce cost. Since particle accelerator research and development continues to be a vibrant field, there will be numerous opportunities to leverage ongoing research.

Glossary

Areal density The integral of the density over a path length traversed by a particle or photon. The areal density of both the fuel and the tamper are of interest in a fusion capsule.

Beam-target fusion In order for fusion to occur, nuclei must overcome the electromagnetic repulsion between them. Beam-target neutron production occurs when nuclei (the beam) are electromagnetically accelerated into target nuclei and fusion reactions occur. This process cannot be energetically favorable, making it undesirable for fusion energy.

Case-to-capsule ratio The ratio of the inner radius of the hohlraum surrounding an inertial confinement fusion capsule to the outer radius of the capsule. The smaller the ratio, the greater the potential for implosion symmetry issues.

Convergence ratio The ratio of the initial target radius to the target radius at stagnation.

DT-equivalent yield The estimated fusion yield that would have been produced by a target if it had been fielded with 50% deuterium and 50% tritium fuel (referred to as DT fuel). The conversion factor from neutron yield produced with pure deuterium to the neutron yield with 50% deuterium and 50% tritium is typically between 50–100 and is dependent on the plasma temperature. The DT-equivalent yield is reported as the total fusion energy released (17.6 MeV per fusion reaction).

Hohlraum A shell whose walls are heated to produce x-rays. Indirect drive fusion uses the uniform soft x-ray emission from the hohlraum walls to drive a fusion capsule implosion.

Laser entrance hole (LEH) window A sub-micrometer to few-micrometer thick membrane that is used to contain gas within a target.

Liner Any conducting shell, typically a cylindrical metal tube, used as the initial configuration of a z-pinch implosion (e.g., as in Magnetized Liner Inertial Fusion targets).

Mix Material other than the fusion fuel, often with an atomic number greater than one, that is introduced into the fuel. This material radiatively cools the fuel at an increased rate, reducing the achievable yield.

PdV work Pressure-driven work done on the fuel through volumetric compression.

Pulsed power driver efficiency The ratio of electrical energy delivered to the target to the energy stored in the capacitor banks of a pulsed power driver.

The classical Z-pinch

The classical z-pinch, sometimes referred to as the Bennett pinch (Bennett, 1934), consists of a steady-state cylindrical plasma column conducting an axial current (see Fig. 1A). The axial current generates an azimuthal magnetic field that exerts a radially inward pressure given by

$$P_{mag} = B^2/2\mu_0 = \mu_0 I^2/8\pi^2 r^2, \quad (1)$$

where B is the azimuthal magnetic field generated by the axial current I flowing through the column, and r is the radius of the plasma column. This magnetic pressure is balanced by a radially outward plasma pressure given by

$$P = nk_B T, \quad (2)$$

where n is the plasma density, k_B is the Boltzmann constant, and T is the plasma temperature. In the classical z-pinch, this pressure balance is established quickly relative to the overall timescale of the pinch, with most time spent in a steady state. The classical z-pinch is more akin to magnetic confinement fusion (MCF) schemes than to inertial confinement fusion (ICF) schemes.

The current flowing through the z-pinch also ohmically heats the plasma. With a large enough current, the energy added through ohmic heating balances the energy lost through radiative losses (Pease, 1957; Braginskii, 1958; Pereira, 1990). For hydrogen, this "Pease-Braginskii" current is 1.4 megaAmperes (MA), independent of the plasma density and pinch radius (Ryutov et al., 2000).

The steady-state z-pinch was one of the first geometries suggested for controlled thermonuclear fusion (Anderson et al., 1958). The aim was to drive the z-pinch to sufficient temperature and density and hold it in that state while fusion energy was produced. Fusion neutron production was observed in this configuration but was the result of **beam-target fusion**. Magnetohydrodynamic instabilities like the "sausage" ($m = 0$) and "kink" ($m = 1$) modes (see Fig. 1B and C) resulted in the plasma column breaking up, generating a large voltage and driving **beam-target fusion** reactions. The realization that such neutron production did not support net-energy production caused classical z-pinch fusion research to dwindle.

The pulsed Z-pinch

Advances in pulsed power technology led to renewed interest in z-pinchs with many studies focused on a configuration known as the pulsed z-pinch (Pereira and Davis, 1988; Ryutov et al., 2000; Sweeney, 2002). The pulsed z-pinch (sometimes called a "fast" or "imploding" z-pinch) also employs an axial current to generate an azimuthal magnetic field and a radially inward force. A key difference between the pulsed z-pinch and the classical z-pinch is that the lifetime of the pulsed z-pinch is short compared to the time to assemble the pinch. In contrast with the classical z-pinch, the pulsed z-pinch is an ICF concept, despite the large magnetic fields

Fig. 1 (A) Cartoon depicting the classical z-pinch geometry. Current flows axially through a cylindrical plasma column and generates an azimuthal magnetic field. The radially inward magnetic pressure is balanced by a radially outward plasma pressure. (B) Cartoon depicting development of the $m = 0$ (sausage) instability. The magnetic field at the plasma surface is inversely proportional to plasma radius, so a small dip in the surface increases the magnetic field. A larger magnetic field applies a greater magnetic pressure locally, decreasing the radius further and creating a positive feedback loop that causes surface perturbations to grow. (C) Cartoon depicting development of the $m = 1$ (kink) instability. If a portion of the plasma has a small offset from the axis, the magnetic field will be greater on the side of the plasma with the dip than on the side with the bulge, resulting in greater magnetic pressure on the side of the dip, which increases the offset and creates a positive feedback loop.

involved in driving the implosion. A subset of pulsed z-pinchs known as magneto-inertial fusion concepts incorporate magnetic fields to retain heat within the fuel during the ICF implosion and stagnation, blurring the lines between ICF and MCF.

In the pulsed z-pinch, typically an annular shell of material is magnetically imploded onto the z-axis, with the implosion duration comparable to the risetime of the driving current pulse. Assuming the radial extent of the annular shell is small compared to the shell radius (i.e., $r \gg \Delta r$), the force acting on the material can be approximated as

$$F_{mag} = -P_{mag}2\pi rh, \quad (3)$$

where r is the outer radius of the material and h is the axial extent of the z-pinch. Substituting Eq. (1) gives

$$F_{mag} = -\frac{\mu_0 I^2}{8\pi^2 r^2} 2\pi rh, \quad (4)$$

which can be simplified to

$$F_{mag} = -\frac{\mu_0 h}{4\pi} \frac{I^2}{r}, \quad (5)$$

indicating that the magnetic force accelerating the material diverges as the material approaches the axis. For a sense of scale, if 20 MA is flowing through a 1-mm-diameter plasma column, the magnetic pressure acting on the column is approximately 250 megabar (Mbar).

When this imploding material reaches the axis, it briefly stagnates, reaching high temperatures and densities for a duration much shorter than the implosion time, and rapidly disassembles. The short stagnation time significantly reduces the importance of the sausage and kink instabilities; however, implosion instabilities, such as the magneto-Rayleigh-Taylor instability (Harris, 1962), take their place. In the magneto-Rayleigh-Taylor instability, much like the classical Rayleigh-Taylor instability (Rayleigh, 1882; Taylor, 1950), when a light fluid (the magnetic field) pushes on a heavy fluid (the plasma), small perturbations in the interface between the two fluids will grow. In a pulsed z-pinch, the outside surface of the plasma is magneto-Rayleigh-Taylor unstable and develops a “bubbles and spikes” pattern during the implosion. This results in a less coherent implosion that impacts the efficiency with which the material can be driven to small radius.

Pulsed power drivers

Pulsed power drivers store electrical energy for long times (seconds to minutes) and discharge that energy over much shorter time-scales (nanoseconds to microseconds) resulting in extremely high electrical powers for short times. For example, the electrical power of the discharge for the world’s largest pulsed power system, the Z machine at Sandia National Laboratories (also referred to as “Z”), can be greater than 80 terawatts (Savage et al., 2011). For a sense of scale, this is roughly an order of magnitude greater than the global power generation capacity, though the discharge lasts for less than one millionth of a second.

Pulsed power development during the 1960s was primarily driven by a desire to conduct radiation effects testing and flash radiography for nuclear weapons applications (Martin, 1996; Van Arsdall, 2007). Radiation effects testing was dominated by multi-megavolt, high impedance ($> 1 \Omega$) systems, but increased interest in low photon energies and high fluences began to grow during that period, leading to lower impedance ($< 1 \Omega$), higher current (~ 1 MA) generators. Many low impedance systems primarily drove electron beams for x-ray production, but early studies of pulsed z-pinchs were also conducted (Turchi and Baker, 1973). Advances in capacitors and pulsed power architectures led to continued increases in the drive current from ~ 1 MA in 100 ns in the 1970s to ~ 27 MA in 100 ns in the 2000s.

Marx generator systems

The Marx generator (Marx, 1924) is the basis of most modern z-pinch pulsed power drivers (see Table 1). A Marx circuit consists of resistors, capacitors, and switches (Fig. 2A and B) arranged such that the capacitors are charged in parallel to the same voltage but discharged in series, creating a voltage equal to the number of capacitors times the individual charge voltage. This is an excellent method to generate large voltages, but because of the relatively high inductance, achieving high currents (multi-MA) with fast rise-times (~ 100 ns) is challenging. To increase the current of a Marx-based pulsed power driver, the current from several Marxes are combined in parallel, resulting in a peak current roughly equal to the number of Marx generators times the individual Marx generator current. The risetime of the Marx current pulse can be reduced by pulse charging a large, low-inductance, water capacitor (McBride et al., 2018) and using a multi-megavolt (MV) laser-triggered spark gap switch (LeChien et al., 2010); however, the faster risetime comes at a cost of reduced pulsed power driver efficiency.

The Z machine at Sandia National Laboratories is an example of a Marx-based system (Savage et al., 2011; Rose et al., 2010). Each Marx has 60 2.6- μ F capacitors, which are routinely charged to 85 kV, resulting in a voltage of 5.1 MV. Z has 36 parallel Marx generators, the combination of which can produce a peak load current of up to 27 MA. Pulse compression allows the $\sim 1 \mu$ s risetime of the Marx current pulse to be reduced to ~ 100 ns. At 85 kV, the energy in the capacitors is ~ 20 megaJoule (MJ), and ~ 2 MJ in electrical energy is delivered to the load; hence, the pulsed power driver efficiency is roughly 10%.

Table 1 An incomplete list of today's pulsed power drivers with the peak currents and risetimes from the references listed.

Driver	Location	Peak current (MA)	Risetime (ns)
Z (Savage et al., 2011)	Sandia National Laboratories, U.S.	27	85
Julong 1 (JianJun et al., 2013; Deng et al., 2016)	China Academy of Engineering Physics, China	8–10	90
Saturn (Sanford et al., 1996)	Sandia National Laboratories, U.S.	7	35
GIT-12 (Bugayev et al., 1997)	Institute of High Current Electronics, Russia	6	1700
ANGARA-5 (Branitsky et al., 1997)	Troitsk Institute of Innovative and Thermonuclear Investigations, Russia	4	90
ZEBRA (Chuvatin et al., 2010)	University of Nevada-Reno, U.S.	1–1.6	100
MAGPIE (Lebedev et al., 1999)	Imperial College, UK	1.4	200–260
COBRA (Greenly et al., 2008)	Cornell University, U.S.	1	95–230
Mykonos (Mazarakis et al., 2010)	Sandia National Laboratories, U.S.	1	70
MAIZE (Gilgenbach et al., 2009; Yager-Elorriaga et al., 2015)	University of Michigan, U.S.	0.6–1	75–140
CESZAR (Conti et al., 2020)	University of California-San Diego, U.S.	0.5–0.9	160–200

Because of feedback from the load to the driver, some variability occurs in the amplitude and risetime of the load current for each driver. All drivers listed are Marx-based with the exception of Mykonos, MAIZE, and CESZAR, which are LTD-based.

Fig. 2 (A) Image of one of the 36 Marx generators that form the Z machine. (B) Circuit diagrams of a 3-stage Marx generator in charging (top) and firing (bottom) states. When charging, all capacitors are connected in parallel to the charging supply, providing the same voltage to each capacitor. When the Marx generator is fired, spark gap switches are closed, connecting the high voltage end of one capacitor to the ground end of the next one. As a result, the voltage is equal to the number of stages times the charge voltage. (C) Circuit diagrams of the smallest element of a linear transformer driver, a “brick,” in charging (top) and firing (bottom) states. The two capacitors are oppositely charged and, when the switch closes, twice the charge voltage is applied across the load. The iron cores inductively limit the current path to ground. (D) Many bricks are connected in parallel to create a “cavity,” which can deliver a 1 MA, 100 kV, 100 ns risetime pulse to a matched load. If a greater voltage is required, several cavities can be stacked to form a “module” with the same current and risetime as an individual cavity but a voltage equal to the charge voltage times the number of cavities. Multiple modules can then be connected in parallel to increase the current of the driver (McBride et al., 2018).

Fast linear transformer drivers

In the late 1990s, an alternative to generate high currents with ~ 100 ns risetimes, called the fast linear transformer driver (LTD), was developed (Kim and Mazarakis, 2020). This concept avoided the less efficient pulse compression schemes needed with Marx systems by using a much larger number of smaller components. In a linear transformer driver, the smallest building block of the system (a “brick”) has the desired risetime, and these bricks are stacked in series and parallel to achieve the desired voltage and current (see Fig. 2C and D). This allows the driver efficiency to be as high as 40% (Mazarakis et al., 2010). In addition, high repetition rate (~ 0.1 Hz) operation of a single LTD cavity has been demonstrated with component lifetimes $> 10^4$ shots (Mazarakis et al., 2009). These characteristics are necessary but not sufficient for a z-pinch-based inertial fusion energy concept. A significant challenge with LTDs is that a high current (~ 60 MA) driver would contain over 10^6 capacitors and 5×10^5 spark gap switches (Stygar et al., 2007; Douglass et al., 2018), making individual component failure likely and tracking failures very challenging. Additionally, the magnetic cores required for each cavity in a large LTD-based driver would significantly add to the cost and timeline.

Fast Marx technologies (Lam et al., 2003) such as impedance-matched Marx generators (Stygar et al., 2017) have also been proposed as z-pinch drivers. Similar to linear transformer drivers, these concepts use a large number of smaller components that enable shorter risetimes than conventional Marx systems, eliminating the need for a pulse compression stage. In contrast to linear transformer drivers, these systems do not utilize magnetic cores.

Explosive pulsed power

An alternate method to generate pulsed high currents is through explosively-driven flux compression (Fowler et al., 1960; Shearer et al., 1968; Sakharov, 1966). Flux compression generators leverage explosives to implode a conductor, amplifying a seed magnetic field within the conductor; this technology provides a path to extremely high currents (~ 100 MA), but with longer risetimes ($\gg 1$ μ s). Flux compression generators are single use as the device is consumed in operation. An example of the use of flux compression generators in pulsed z-pinch studies is given below in the section on magneto-inertial fusion.

Radiation production with pulsed Z-pinch

Fusion can be produced directly with a pulsed z-pinch through the implosion of a deuterium column. This is the closest analog of the pulsed z-pinch to the classical z-pinch. Typically, the load is gaseous deuterium that has been injected into the load region, spanning the anode-cathode gap (Bailey et al., 1982). Deuterium gas puffs can be fielded on large drivers to create significant neutron yields (Klir et al., 2014; Coverdale et al., 2007). A drawback to this approach is that the quantity of gas required is large, so the fielding of tritium is somewhat impractical. Excluding tritium reduces the potential neutron production by nearly 2 orders of magnitude. Moreover, thermonuclear neutron production in gas puff z-pinch scales as the current to the fourth power (Welch et al., 2011), so scaling to large yields ($\gg 10$ MJ) is not feasible even with tritium. Additionally, the fuel density required at high current (> 80 MA) is beyond what is possible to generate with a puffed gas nozzle. Lastly, current coupling has proven problematic (Harvey-Thompson et al., 2016a) and may remain an issue on future high current drivers.

A z-pinch can also be used for x-ray production (e.g., metal wire array, argon gas puff) (Stallings et al., 1976), where the x-ray energy spectrum is dependent on the wire material. Low atomic number materials like aluminum, argon, iron, and copper produce K-shell x-rays (Ampleford et al., 2014) for radiation effects tests. High atomic number materials like tungsten produce a softer spectrum of continuum x-rays to drive ICF capsules (Sanford et al., 1999) and laboratory astrophysics studies (Rochau et al., 2014; Bailey et al., 2015).

In the 1990s and 2000s, z-pinch ICF research focused on arrays of fine metal wires (Matzen, 1997; Matzen et al., 2005), based largely on record-setting soft x-ray yields on Saturn (Sanford et al., 1996) and Z (Deeney et al., 1998). The innovation that led to significant increases in x-ray production was using many (~ 100 – 500) fine wires of ~ 10 μ m diameter to produce a more uniform implosion. X-ray yields as high as 2 MJ and x-ray powers as high as 330 TW have been produced on Z with a peak load current of 20–21 MA (Jones et al., 2014). The success of high-wire-number z-pinch on Saturn and Z led to numerous university studies of wire initiation and array implosion dynamics at ≤ 1 MA (Duselis and Kusse, 2003; Kantsyrev et al., 2006; Bland et al., 2007; Shelkovenko et al., 2007; Douglass et al., 2008; Gomez et al., 2008; Hall et al., 2008; Zier et al., 2009). Additionally, z-pinch studies at universities led to spin-off designs to study astrophysically-relevant plasmas in the laboratory (Bott-Suzuki et al., 2015; Hare et al., 2017; Lebdev et al., 2019).

The main goal of z-pinch studies on Z in the 1990s and 2000s was to develop an x-ray source capable of imploding a spherical ICF capsule while demonstrating the necessary shock timing and symmetry control. Many z-pinch concepts were investigated, and two promising concepts were identified. The cylindrical double-ended hohlraum (Matzen, 1997; Hammer et al., 1999; Matzen et al., 2005) and the cylindrical dynamic hohlraum (Smirnov, 1991; Matzen, 1997; Brownell et al., 1998) were thoroughly studied (see Fig. 3A and B, respectively).

The double-ended hohlraum consists of two wire arrays, each housed in a primary hohlraum, with a secondary hohlraum containing a fusion capsule between them. X-rays from the z-pinch drive the primary hohlraums. Those two hohlraums then drive the secondary hohlraum, and the secondary hohlraum drives the fusion capsule. The secondary hohlraum and capsule geometry share a lot of similarities with the laser indirect drive (Regan, 2021) configurations being tested on the National Ignition Facility (NIF) (Finnegan, 2021). A key difference is that the hohlraum containing the capsule is driven with soft x-rays, which avoids or reduces some issues associated with heating the hohlraum with laser beams (e.g., cross-beam energy transfer). Heating up the primary hohlraums to heat a secondary hohlraum causes some inefficiency; however, this design provides excellent irradiation symmetry of the capsule (Cuneo et al., 2012). As a point of reference, two 9 MJ z-pinch are believed to be sufficient to drive a capsule capable of creating ~ 500 MJ of fusion yield; these z-pinch would require a 65–70 MA driver (Vesey et al., 2007).

The dynamic hohlraum consists of a wire array surrounding a low-density foam that houses the capsule. The wire array implodes and strikes the foam, generating a radiative shock. The tungsten plasma surrounding the foam acts as a hohlraum and continues to implode toward the capsule, increasing the radiation temperature. On Z, this configuration produced a deuterium-deuterium neutron yield up to 3.5×10^{11} (0.07 kJ DT-equivalent yield), which was the highest at the time from an indirect drive concept (Ruiz et al., 2004; Rochau et al., 2007). Numerical scaling studies also indicated the dynamic hohlraum could produce ~ 500 MJ yields with ~ 60 MA drive currents (Mehlhorn et al., 2003); however, the lower load impedance would require a driver with significantly less stored energy than the double-ended hohlraum (Cuneo et al., 2012). Although the dynamic hohlraum would be more efficient at coupling energy, the capsule implosion symmetry is challenging as a result of the shrinking case-to-capsule

Fig. 3 (A) Cartoon depicting the key stages of the cylindrical double-ended hohlraum concept. Initially current (green) flows through two arrays of fine tungsten wires (red) as shown in the left image. The tungsten wire arrays become plasma, implode, stagnate on axis, and begin emitting x-rays (orange) as shown in the middle image. The **hohlraum** walls are heated and begin radiating soft x-rays, which implode a spherical fusion capsule (blue) as shown in the right image. (B) Cartoon depicting the key stages of the cylindrical dynamic hohlraum concept. Initially a current (green) flows through an array of fine tungsten wires (red) as shown in the left image. The tungsten wire array becomes plasma, implodes, and collides with a foam (yellow) generating a radiating shock (purple) as shown in the center image. The tungsten continues to implode while serving as the walls of the **hohlraum** to implode the spherical fusion capsule (blue) as shown in the right image.

ratio (Cuneo et al., 2012). Efforts to improve the dynamic hohlraum on Z ceased in the 2000s, but innovation of the concept has continued on the Julong-1 facility in China (Huang et al., 2017; Meng et al., 2017; Wu et al., 2018).

While wire array z-pinch source development on Z has continued for radiation effects sciences testing, efforts to use z-pinzches for indirect drive fusion on Z largely stopped in the mid-2000s. Two major factors contributed to this dramatic change in focus - the driver-target coupling efficiency and the start of operations on the NIF.

For indirect drive, the coupling efficiency includes (1) energy stored vs. electrical energy delivered to the load, (2) electrical energy to the load vs. x-ray energy radiated by the load, (3) x-ray energy radiated vs. energy absorbed by the capsule, and (4) energy absorbed vs. fuel thermal energy at stagnation (Cuneo et al., 2012). In an effort to address these inefficiencies, a magnetic direct drive configuration was developed, where the magnetic pressure supplied by the drive current is directly applied to a capsule. In magnetic direct drive only (1) energy stored vs. electrical energy delivered to the load and (2) electrical energy to the load vs. thermal energy at stagnation must be considered. Cutting out the steps where x-rays are generated and absorbed potentially increases the efficiency significantly, although it is important to note that indirect drive has been thoroughly studied for many years, making that concept much more mature than magnetic direct drive (Cuneo et al., 2012).

The second event that drove a shift in ICF research on Z was start of operations at the NIF. Significant progress was made in z-pinch-based indirect drive (sometimes called x-ray indirect drive) as a viable path to producing fusion, but the **hohlraum** temperatures generated in Z experiments did not allow the study of ignition scale capsule implosion physics, which was the largest remaining uncertainty for the concept. Efforts on the NIF, which was expected to generate significantly higher **hohlraum** temperatures, would be focused on studying implosion physics in ignition scale capsules. A goal of the ICF studies on the NIF was to achieve ignition, but there was an expectation that achieving > 10 MJ yields would require a larger driver than the NIF, which could take the form of z-pinch-based x-ray indirect drive on a next-generation pulsed power facility.

Magneto-inertial fusion

Between the limit of high density, small volume, and short duration plasmas characteristic of ICF and the opposite limit of low density, large volume, and long duration plasmas typical of MCF, exists a continuum of magneto-inertial fusion (MIF) concepts (Lindemuth and Kirkpatrick, 1983; Basko et al., 2000). In all MIF concepts, a magnetic field is applied to a fusion fuel-containing target, which is then imploded. The implosion increases the fuel temperature and density, and the shell surrounding the hot fuel acts as a tamper, providing the inertial confinement. The magnetic field reduces the rate at which thermal conduction losses occur between the fuel and the outer layers of the target, and the magnetic field also helps trap charged fusion products within the fuel, reducing the **areal density** requirement for self-heating. Implementations of MIF range from simply applying a magnetic field to an ICF capsule to improve its performance (Chang et al., 2011; Perkins et al., 2013) to imploding a low-density plasma torus within a metal shell (Degnan et al., 2013). MIF configurations in which current passes through a cylindrical target, causing it to implode, are a type of pulsed z-pinch and are referred to as magnetic direct drive fusion configurations.

One of the earliest MIF implementations was MAGO (magnitnoye obzhatiye, or magnetic compression), studied in Russia starting in the 1970s (Chernychev et al., 2016). In MAGO a hot, magnetized plasma is formed with an explosively-driven flux compression generator; a cylindrical or spherical **liner** is then imploded, compressing the hot plasma. This geometry is z-pinch-like, although the **liner** implosion is not necessarily driven by a current. Recently, research was conducted in the U.S. on Shiva Star to generate, transport, and crush a field reversed configuration; however, the lifetime of that configuration was insufficient for compression (Degnan et al., 2013). Z-pinch-like MIF experiments have also been conducted on the University of Rochester's Omega laser facility by illuminating the target surface to compress a cylindrical target containing magnetized fuel (Gotchev et al., 2009). Although magnetic pressure did not cause the implosion, the geometry was similar to that of z-pinch concepts. Neutron production in magnetized experiments was greater than in unmagnetized ones, but because of large variability in the performance of the unmagnetized targets, it is challenging to specify by how much. Other non-z-pinch research in MIF has included the Phi-target, which was tested on a predecessor of Z at Sandia National Laboratories (Chang et al., 1977; Sweeney and Farnsworth, 1981); the plasma liner experiment at Los Alamos National Laboratory, which creates standoff between the driver and target by injecting the fuel and **liner** with plasma guns (Hsu et al., 2012; Merritt et al., 2013); and acoustically-driven magnetized target fusion at General Fusion (Laberge, 2008).

Introduction to magnetized liner inertial fusion

In the late 2000s, a magneto-inertial fusion concept known as Magnetized Liner Inertial Fusion (MagLIF) was developed (Slutz et al., 2010). Similar to other MIF concepts, MagLIF relies on strong magnetic fields to limit thermal conduction losses and a **liner** implosion to compress and heat the fuel to fusion conditions. A major difference between MagLIF and most other MIF concepts (the Omega experiments listed above being the exception) is that the implosion occurs on a much shorter timescale (~ 100 ns), which enables the use of a significantly higher initial density fuel and open magnetic field lines within the target.

In MagLIF, an axial magnetic field of 10–30 tesla (T) is applied using Helmholtz-like coils to a 10-mm tall, 5-mm outer diameter, 0.5-mm wall thickness metal cylinder, which contains fusion fuel (see Fig. 4). Magnetization of the target is on a multi-ms timescale, which allows the magnetic field to diffuse through the conductors connecting the generator to the target as well as the target itself (Rovang et al., 2014).

A few-ns, multi-kJ laser pulse enters the magnetized target axially through a thin plastic foil, heating the fuel to hundreds of eV. The fuel density is roughly 10% of the critical density for a frequency-doubled Nd:YAG laser (527 nm), allowing the laser to penetrate and heat the fuel through inverse bremsstrahlung absorption. The current from Z passes axially through the target and causes it to implode with a peak velocity of 70–100 km/s.

The implosion velocity in MagLIF is slow by ICF standards but better matched to the 100-ns risetime of Z and allows for relatively thick target walls that are more robust to feedthrough of instabilities developed on the exterior of the target. The slow, stable

Fig. 4 (A) Cross section of MagLIF load hardware rendering showing the target, applied magnetic-field coils, and final transmission line. (B) Cartoon depicting the three MagLIF stages (top) and snapshots from a 3D magnetohydrodynamic calculation showing the same three MagLIF stages (bottom). Initially an axial magnetic field is applied to the target, which contains gaseous fuel. Next a laser enters the target through a thin plastic foil (a **laser entrance hole window**) to preheat the fuel prior to the start of the implosion. The metal walls of the target implode, compressing the fuel and magnetic flux contained in the target to achieve multi-keV temperatures and multi-kiloTesla magnetic fields. (C) X-ray self-emission image from the fuel at stagnation in a MagLIF experiment.

implosion necessitates the laser preheat; without it, the fuel could not reach multi-keV temperatures. Instead, a **convergence ratio** greater than 50 would be required, and instabilities would make such high **convergence ratios** unrealistic. The magnetic field serves (1) to limit thermal conduction losses from the preheated fuel to the target walls, enabling the preheat energy to be retained and augmented through the **PdV work** of the implosion, and (2) to trap charged fusion products at stagnation, enabling them to deposit their energy into the fuel to produce additional heating.

MagLIF experimental progress

The first Z experiments with the axial magnetic field, laser preheat, and **liner** implosion stages combined were conducted in November 2013 (Gomez et al., 2014a). The experiments used deuterium gas as the fuel, a 10 T axial field, 0.5 kJ laser preheat energy deposited, and 18 MA peak load current. The highest performing experiment produced a burn-averaged ion temperature of 1.9 keV and a deuterium-deuterium neutron yield of 5.3×10^{11} (0.07 kJ **DT-equivalent yield**). Over the next few months, subtle changes to the target geometry gave yields as high as 2.0×10^{12} (0.3 kJ **DT-equivalent yield**) (Gomez et al., 2014a).

Subsequent improvements to the target design have primarily focused on reducing radiative losses during the long (> 50 ns) delay between preheat and stagnation. Since bremsstrahlung radiation goes as roughly atomic number cubed, any **mix** with an atomic number greater than one will enhance radiative losses relative to the deuterium fuel, with higher atomic number materials having a significantly greater effect. The **laser entrance hole (LEH) window** foil thickness was reduced to (1) decrease the amount of hydrocarbon window material available to be driven into the fuel and (2) roughly double the preheat energy coupled to the fuel to around 1 kJ (Gomez et al., 2015; Harvey-Thompson et al., 2019). The enhancement in coupled preheat energy has increased the importance that all fuel-facing components within the target should be made from low atomic number materials (Knapp et al., 2019; Gomez et al., 2019). Switching several components from aluminum to beryllium increased the ion temperature to 2.2 keV and the neutron yield to 3.2×10^{12} (0.45 kJ **DT-equivalent yield**) by mid-2015.

Efforts to improve the quality of the laser beam spot and to modify the laser pulse shape (Harvey-Thompson et al., 2018) have increased the laser energy deposited to 1.4 kJ. An advanced applied magnetic field coil has enabled applied fields of 16 T without obstructing radial diagnostic access to the target, and modifications to the final transmission line have increased the peak load current to 20 MA. Experiments with these improvements have produced an ion temperature of 3.1 keV and a yield of 1.1×10^{13} (2.0 kJ **DT-equivalent yield**) (Gomez et al., 2020).

Scaling MagLIF results to high yields

The improvements to the MagLIF platform described above have enabled parametric scans of the applied magnetic field, coupled preheat energy, and peak current. The trends in the data are well matched by magnetohydrodynamic simulations (Slutz et al., 2018; Gomez et al., 2020), providing confidence in scaling these results to high yield. Additional insight into the scaling has been gained through experiments on the Omega laser at 1/10th spatial scale (Barnak et al., 2017; Davies et al., 2017; Hansen et al., 2020). In the Omega experiments, the **liner** compression was provided by laser direct drive of a plastic cylinder (Hansen et al., 2018) as opposed to magnetic direct drive of a metal cylinder.

Given the consistency between the data and the simulations, what might be achieved with a significantly larger pulsed power driver has been estimated. MagLIF scaling simulations indicate that multi-MJ yields and capsule breakeven might be achieved with a current pulse of ~ 45 MA and that tens of MJ of fusion yield (approaching facility breakeven) might be produced through volume burn with a current pulse of ~ 60 MA (Slutz et al., 2016). These two-dimensional simulations indicate ~ 60 MA is the threshold where burning DT ice becomes possible, which might enable high gain and hundreds of MJ of fusion yield (Slutz and Vesey, 2012; Sefkow et al., 2014; Slutz et al., 2016). In addition to the drive current being significantly increased, the coupled laser energy and applied magnetic field would also be increased to 30–60 kJ and 30 T, respectively, to achieve higher yields. These are large extrapolations outside of the explored parameter space, so careful work is needed to understand the uncertainties associated with these predictions.

Scaling uncertainties

To bolster confidence in scaling the MagLIF concept to high yields, the key uncertainties have been identified, and efforts to understand and mitigate these uncertainties are underway. These key uncertainties are laser preheat energy coupling, target magnetization, current coupling, implosion stability, and enhanced radiative loss through **mix**. Nearly 100 MagLIF experiments have been conducted on Z since 2013, with many focused on addressing these five scaling uncertainties.

Laser preheat energy coupling

Although laser preheat has been a consistent challenge for MagLIF, efforts to understand this stage via experiments (Geissel et al., 2016, 2018) with the Z-beamlet laser (Rambo et al., 2016), independent of Z, have led to continued improvement. Experiments (Harvey-Thompson et al., 2015, 2016b) have also been conducted on the Omega-Extended Performance laser facility (Waxer et al., 2005), which has enhanced beam smoothing capabilities as well as the ability to investigate laser wavelength effects.

To date, the maximum laser energy coupled to the fuel in a MagLIF experiment was 1.7 kJ with $\sim 70\%$ coupling efficiency. Further improvements in preheat energy coupling efficiency will require either cryogenic cooling to reduce the fuel pressure, which

will allow the thickness of the **LEH window** to decrease (Awe et al., 2017), or will require an alternative method to reduce the effects of absorption in or backscatter from the **LEH window**. One such alternative is the laser-gate concept (Slutz et al., 2018; Miller et al., 2020) in which the window is rapidly opened just before the laser arrives. Given the infrastructure of the Z-beamlet laser, the maximum laser energy that could be delivered to a MagLIF target is $\sim 5\text{--}6$ kJ; hence, 4–5 kJ preheat energies appear plausible on Z and are roughly optimal (Slutz et al., 2018) for the 20–22 MA maximum peak load current expected in Z experiments.

Given the order of magnitude difference in preheat energy between what is possible on Z and what is required for ignition, efforts to study ignition-scale laser preheat have become a focus for MagLIF. Preheat experiments are being conducted using four beams of the NIF. In these experiments, more than 30 kJ of laser light can reach a surrogate MagLIF target, enabling studies of ignition-scale preheat energy coupling. An applied magnetic field capability of > 20 T has also been developed at the NIF in support of this effort.

Target magnetization

Magnetization of a MagLIF target is challenging because radial diagnostic access is strongly desired. Magnetic coil designs that can reach 25–30 T but do not maintain diagnostic access are available (Rovang et al., 2014). Efforts to develop internally-reinforced coils to enable high magnetic fields while preserving diagnostic access began in 2017. Such a coil configuration, which magnetized a MagLIF target to 22 T, was first demonstrated in offline tests conducted in early 2020. Further improvements to this design, which are expected to provide 25–30 T, are under development. An alternative magnetization scheme has been proposed (Slutz et al., 2017); for that scheme, the main drive current is directed in a helical path through the target in order to generate an axial magnetic field of $\sim 50\text{--}200$ T within the target (Shipley et al., 2019). The implosion stability of such a helically structured target is being investigated. Scaling calculations indicate that the optimal field for MagLIF is close to 50 T when the peak load current is roughly 20 MA (Slutz et al., 2018) and drops to 20–30 T when the current is 40–60 MA (Slutz et al., 2016).

Current coupling

Understanding electrical power flow to a target is critical for pulsed power-based systems; hence, a focused effort to model and obtain data on Z's power flow began in the late 2010s. The potential for plasmas to form increases as the current density is increased in a transmission line, and these plasmas have been linked to current losses (Rose et al., 2008; Gomez et al., 2017; Hutsel et al., 2018; Bennett et al., 2019). Moreover, in higher current drivers, plasmas will form over a larger radial extent of the transmission lines, which increases the uncertainty in scaling the current coupling. About 10 dedicated power flow physics experiments have been conducted per year, with an initial focus on developing a suite of visible light and charged particle diagnostics (Gomez et al., 2014b; Gomez et al., 2017; Dolan et al., 2018; Datte et al., 2020). The primary goal of such experiments is to obtain constraining datasets against which power flow simulations can be vetted to increase confidence in extrapolating to a future facility that would deliver 40–60 MA to a target.

Implosion stability

Achieving implosion stability is critical as the disassembly time at stagnation in an ICF target depends on the integrity of the tampering material. Magnetohydrodynamic simulations of **liner** implosions can match the general behavior observed in magnetically-driven implosions (Martin et al., 2012), but some observations are puzzling. Identifying and understanding the missing physics in these simulations is ongoing. A few examples are given below.

Studies of the development of instabilities in experiments with a prescribed instability seed are well predicted by simulations (Sinars et al., 2010); however, a thorough study of development of instabilities in smooth surface targets has shown an unexpected level of azimuthal correlation of instability structures (McBride et al., 2012). The cause of such behavior was hypothesized to be an electrothermal instability (Oreshkin et al., 2004; Peterson et al., 2012) that created a large seed for the magneto-Rayleigh-Taylor instability. That hypothesis is consistent with experiments in which a dielectric coating was applied to the exterior of a target to tamp expansion of the electrothermal plasma, resulting in a significant reduction in the magneto-Rayleigh-Taylor amplitude (Peterson et al., 2014; Awe et al., 2016).

In **liner** implosions with an applied axial magnetic field, the instability structures that developed were helical (Awe et al., 2013). However, these structures were expected to be azimuthal because, at the time the **liner** began to implode, the azimuthal magnetic field was much larger than the axial field applied to the target (Awe et al., 2014). Several hypotheses to explain these structures have been proposed (Ryutov et al., 2014; Sefkow, 2016; Seyler et al., 2018), and efforts to determine the origins of the helical instability experimentally are underway. Understanding this behavior is important because helical structures are seen in the fuel column at stagnation, indicating feedthrough of the instability from the exterior surface of the **liner** to the interior surface. Prediction of such behavior in simulations may allow the development of mitigation schemes.

Mix

The introduction of mid- or high-atomic number material into the fuel is a concern for all fusion concepts; the enhanced radiative losses that result can significantly degrade target performance. In MagLIF, the implosion duration is significantly longer than in a typical ICF implosion, which would enhance the detrimental impact of **mix** introduced early in a MagLIF implosion. Typically, the laser preheat timing is chosen to maximize the work that the **liner** does on the fuel during the implosion; however, this also maximizes the radiative losses for any laser-induced **mix** in a MagLIF target. The two main sources of laser-induced **mix** are the **LEH window** material and material liberated from the inner surface of the target via direct laser strike. For a well-designed laser

pulse shape, laser spot size, and target fuel density, injection of the window material can be essentially eliminated (Harvey-Thompson et al., 2018). Similarly, a well-designed laser pulse should not strike any surface within the target (Weis et al., 2021) and, if all components within the target are coated in deuterium ice, any mix would have a minimal impact on target performance (Slutz et al., 2018).

The future of pulsed power and Z-pinchs

Z-pinch-based fusion efforts require a larger drive current than is available today. Several concepts explored on present-day pulsed power facilities are predicted to reach tens to hundreds of megajoule yields with ~ 60 MA drive current, according to simulations (Mehlhorn et al., 2003; Vesey et al., 2007; Slutz et al., 2016). A number of large-scale facilities have been proposed that could enable such tests. In Russia, the Baikal generator, a Marx-based facility designed to produce 50 MA with a 100–300 ns risetime, was proposed but has yet to be built (Grabovsky et al., 2001). In China, two facilities have been proposed based on fast linear transformer driver technology, with construction of one test module (out of 60) in progress for the larger, 60-MA, 120-ns risetime facility (Chen et al., 2019; JianJun, 2020). While the second proposed Chinese facility (CZ30) is a bit smaller at > 30 MA, it would still be the highest current pulsed power facility in the world (Mao et al., 2019). In the United States, both Marx-based and linear transformer driver-based concepts for a next generation pulsed power facility have been proposed (Stygar et al., 2007, 2015; Douglass et al., 2018; Sinars et al., 2020) for ~ 45 –65 MA drive currents.

A key milestone for z-pinch-based ICF, which would require a higher current driver than is operational now, is to produce more fusion energy from a target than the electrical energy invested in the target. Simulations suggest that this threshold could potentially be reached with a fusion yield of ~ 1 MJ and a peak current of ~ 30 MA (Slutz et al., 2016). A longer-term goal is to demonstrate high gain, which would require burning DT ice to produce hundreds of MJ (Hammer et al., 1999; Mehlihorn et al., 2003; Slutz and Vesey, 2012; Slutz et al., 2016). Demonstration of a single-shot, high-gain configuration is an objective for stockpile stewardship and inertial fusion energy; however, considerable additional research would be required to apply such a configuration to inertial fusion energy (Sinars et al., 2015).

Glossary

Activated Material Material that has experienced neutron irradiation resulting in neutron capture and the production of radioactive isotopes.

Additive Manufacturing Commonly referred to as “3-D printing” this refers to a manufacturing technique that builds components by layering a powder that is melted by a precision laser or electron beam according to a computer design drawing.

Artificial Intelligence The theory and development of computer systems to be able to perform tasks that normally require human intelligence such as decision-making.

*Dedication to Professor/General Dr. Guillermo Velarde.

Beta-Decay In nuclear physics, beta decay (β -decay) is a type of radioactive decay in which a beta particle (fast energetic electron or positron) is emitted from an atomic nucleus, transforming the original nuclide to an isobar of that nuclide, that is, a material with the same mass number but a different number of protons.

Blackbody The amount of radiation energy emitted from a surface at a given wavelength depends on the material of the body and the condition of its surface as well as the surface temperature. Various materials emit different amounts of radiant energy even when they are at the same temperature. A body that emits the maximum amount of heat for its absolute temperature is called a blackbody.

Debris After the target completes its fusion burn, the material remaining, consisting of unburned and very energetic T and D atoms, plastic CH material in a plasma state, Be and/or C from the capsule, and/or Pb (or other high Z material) in a plasma state that had been used for the hohlraum; expands and impacts the chamber first wall.

Deep Learning (DL) A subset of machine learning applications that teaches itself to perform a specific task with increasingly greater accuracy, without human intervention.

Displacements per Atom A measure of the amount of radiation damage in neutron-irradiated materials where 10 dpa means each atom in the material has been displaced from its site within the structural lattice of the material an average of 10 times due to interactions between the atoms and the energetic neutrons irradiating the material.

Efficiency-Gain Product The efficiency of whatever driver is being used in an IFPP multiplied by the gain that this driver creates, economic studies have shown, should be a value of about 10 in order to be economical and lead to a competitive cost of electricity eV Condition: Temperature greater than an eV or 11,000 Kelvin.

FAIR Facility for Anti-proton and Ion Research being built at the GSI in Germany, will be one of the largest and most complex accelerator facilities in the world. The FAIR accelerator facility will have the unique ability to provide particle beams of all the chemical elements (or their ions), as well as antiprotons. The particles will be accelerated to 99% of the speed of light. At the heart of the facility is an underground ring accelerator with a circumference of 1100 m. The existing accelerator facility will serve as the injector for the new FAIR facility which will start operation in 2025.

Fermi degenerate state Fermionic matter in highly dense state in which the Pauli exclusion principle exerts significant pressure in addition to, or in lieu of thermal pressure. The description applies to matter composed of electrons, protons, neutrons or other fermions.

Fermi-Dirac Statistics In quantum statistics, a branch of physics, Fermi-Dirac statistics describe a distribution of particles over energy states in systems consisting of many identical particles that obey the Pauli exclusion principle. It is named after Enrico Fermi and Paul Dirac, each of whom discovered the method independently.

Fermions In particle physics, a fermion is a particle that follows Fermi-Dirac statistics and generally has half odd integer spin such as $1/2$, $3/2$, etc. These particles obey the [Pauli exclusion principle](#). Fermions include all quarks and leptons, as well as all composite particles made of an odd number of these, such as all baryons and many atoms and nuclei. Some fermions are [elementary particles](#), such as electrons, and some are composite particles, such as protons. According to the [spin-statistics theorem](#) in relativistic quantum field theory, particles with [integer](#) spin are [bosons](#), while particles with half-integer spin are fermions. Composite fermions, such as protons and neutrons, are the key building blocks of [everyday matter](#). The name fermion was coined by English theoretical physicist Paul Dirac from the surname of Italian physicist Enrico Fermi.

First Wall The first surface in a IFPP chamber that receives the IFE target emissions.

Flash-Lamped Pumped Tubes filled with xenon gas discharge its line emissions into Nd-doped phosphate glass acting as laser amplifiers for the NIF.

Frequency Up-Conversion The Nd laser emission line of 1.056 nm is frequency doubled to 528 nm and the frequency tripled to 352 nm to use for driving an ICF direct or indirect drive target.

Fuel Configuration at Stagnation This is a key measurement to make during current NIF experiments that shows whether the hotspot and dense fuel regions are properly formed and are free of mix.

Fusion A nuclear reaction where two light nuclei merge and produce products with different mass numbers than the reactants.

Gain The yield of an ICF target divided by the driver energy that caused the yield.

GSI GSI Helmholtzzentrum für Schwerionenforschung is a German research center in Darmstadt, Germany that operates a unique large-scale accelerator for heavy ions.

Heavy Ion "Heavy" by convention is an atom that has an atomic number greater than 13 and is ionized so that it can be accelerated by magnetic fields.

HIAF The High Intensity heavy ion Accelerator Facility is a new facility planned in China for heavy ion related research. The key features of HIAF are unprecedented high pulse beam intensity and versatile operation mode. The facility will be commissioned in 2025.

Hotspot Mix The baseline approach to ICF creates a "hotspot" in the center of the assembled fuel where the fusion reactions initiate leading to a propagating burn wave into the cold dense fuel. If material enters the hotspot region because it mixes in during the compression phase, then the hotspot is degraded and cannot ignite the fusion fuel.

ICF Target This refers to either a directly or indirectly driven capsule encased in other materials to convert the particular driver energy being used into an ablative force to drive the capsule to fusion conditions.

Ignition The condition achieved in an ICF capsule where hot DT fuel in a low density region in the center of the fuel region undergoes fusion and the alpha particles released heat the nearby much higher density but colder fuel resulting in a substantial increase of the ion temperature and more fusion reactions leading to about 250 kJ of net fusion yield for a NIF scale target.

Inertial Fusion Power Plant A facility that generates electricity by harnessing the fusion reaction in a pulsed mode.

ITEP Institute for Theoretical and Experimental Physics located in Moscow, Russia.

Laser Light Amplified by the Stimulated Emission of Radiation that, applied to IFE, means collimated photons of a single wavelength that can be focused to single spot.

Low Activation Tendency of a material to activate with radioisotopes with short half-lives.

Machine Learning (ML) A field within artificial intelligence that keeps a computer's built-in algorithms current regardless of changes in its environment.

Material Damage Fusion neutrons penetrate into materials causing atomic displacements in the lattice structure of the molecules making up the material; when excessive this can change materials properties such as tensile strength.

Molecular Dynamic Simulation Molecular dynamics (MD) simulation is a widely used approach to study the time evolution of a system of "particles," typically atoms or molecules with defined properties.

Neutralized Drift Compression Experiment II (NDCX-II) A linear induction accelerator located at Lawrence Berkeley National Laboratory where 0.8–1.2 MeV helium ion pulses with intensity up to 1.5×10^{18} ions/mm²/s in a few ns pulses are available where the number of ions is tunable up to 10^{11} ions/pulse and the beam spot sizes can be tuned from 1 mm² to 1 cm² and the repetition rate is 1.3 shots/min (Seidl et al., 2018).

Neutron Heating This describes a process where neutrons undergo elastic or inelastic collisions with atoms in a material the neutron has entered the result of which is energy is transferred to the target atom and the neutron moves on with less energy. The material realizes this effect as an increase in its temperature or heating.

Neutron Shielding Materials that are effective in slowing down and/or absorbing neutrons.

Neutronics Analyses that describe the effects of neutrons.

Neutrons One of the products of the fusion reaction between Deuterium and Tritium; sub-atomic particle with nearly the mass of a proton but with no charge.

Object Kinetic Monte Carlo Simulation A Monte Carlo method computer simulation intended to simulate the time evolution of some processes occurring in nature - typically processes that occur with known transition rates among states. These rates are inputs to the KMC algorithm, the method itself cannot predict them.

Pauli Exclusion Principle The assertion that no two fermions can have the same quantum number that is occupy the same quantum state at the same time.

Polar Drive Using the NIF beams to irradiate a direct drive target. It is called "polar" because there are no "equatorial" beams on the NIF that would complete a direct drive configuration.

Pulsed Power Applied to IFE, the delivery of a very large currents of electricity (> Mega-Amps) in a very short time (100 ns) to an anode-cathode gap that contains a direct drive DT target.

Relativistic Heavy Ion Collider The RHIC is the first machine in the world capable of colliding heavy ions, which are atoms which have had their outer cloud of electrons removed. RHIC primarily uses ions of gold, one of the heaviest common elements, because its nucleus is densely packed with particles, and collide them at nearly the speed of light.

Residual Radioactivity Activated material that has isotopes that are long enough that decay radiation is persistent for a period of time.

Shell Asymmetry Any aspect of an ICF capsule that would make it deviate from a perfect spherical surface.

Tritium A radioactive isotope of hydrogen with a half-life of 12.32 years. The nucleus contains one proton and two neutrons.

Ultra-high Vacuum Vacuum of 10^{-8} Torr or lower.

Warm Dark Matter A popular (if speculative) "dark matter" particle, one that has some ability to interact with very light particles that move close to the speed of light forms one of several possible warm dark matter (perhaps more accurately called interacting dark matter) scenarios (Bose et al., 2019).

X-Rays The region of the capsule where the fusion reactions take place emits X-rays in conjunction with these reactions; in addition, the very hot debris also emits X-rays. ICF X-rays are photons from energies as cold as 1 eV and as hot as several hundred keV.

Yield The net energy released by an IFE target from fusion reactions.

Dr. Guillermo Velarde was Professor Chair of Nuclear Physics since 1973 at the Industrial Engineering College of the Universidad Politécnica de Madrid and General in the Division of the Spanish Air Force. Professor Velarde began at the Spanish Atomic Energy Commission in 1958. In the early 1970s he initiated research in Inertial Confinement Fusion Physics (ICF) with a small but outstanding group developing several integrated/coupled codes for Radiation-Hydrodynamic and Particle Transport Physics (NORMA, CLARA and NORCLA) to study the implosion and burning of fusion-fission and pure fusion targets. The codes' results, published in various journals starting in 1976, had a large international impact in the fusion scientific community, attracting the interest of laboratories such as Kernforschungszentrum Karlsruhe (Germany), Lawrence Livermore National Laboratory (USA), Institute of Laser Engineering Osaka University (Japan), Laboratory for Laser Energetics at the University of Rochester, Lebedev Institute Moscow (Russian Federation) and Commissariat d'Énergie Atomique (France). Guillermo published in 2007 to critical acclaim a history of early ICF research activities with original contributions by early researchers called "Inertial Confinement Nuclear Fusion: A Historical Approach by Its Pioneers" (Velarde and Carpintero-Santamaria, 2007). In 1981 Guillermo founded the Instituto de Fusión Nuclear (IFN) (today re-named Instituto de Fusión Nuclear "Guillermo Velarde") within the Universidad Politécnica de Madrid with a small group of scientists, C. Ahnert, J.M. Aragones, J.M. Martinez-Val, E. Minguez, N. Carpintero, J. M. Perlado, and later P. Velarde and J. Sanz. From its start the IFN initiated many high level international scientific relationships in research fields dedicated to generation of electrical power from Inertial Confinement Fusion. This effort played a fundamental role in the promotion of research for Inertial Confinement Fusion in EURATOM, through its decision-making committees such as the Consultative Committee EURATOM Fusion and the Keep in Touch ICF Programs throughout the Framework Programs V, VI, and VII. Guillermo was president of the Keep in Touch from 1998 to 2006. These programs continue today in EuroFusion with the "Towards Inertial Fusion Energy Project." Radiation-Hydro codes for target design together with new multiscale modeling of key mechanisms in reactor development in Heavy Ion and Laser Inertial Fusion Energy were the goals under his direction. Professor Velarde also reinforced the role of the International Atomic Energy Agency for Inertial Fusion Energy (IFE). He, together with many other outstanding scientists he recruited, wrote the IAEA book on Energy from Inertial Fusion. He also proposed and led several successful IAEA Coordinated Research Projects in Inertial Fusion. Guillermo wrote/co-wrote 14 books, including "Quantum Mechanics" (2002) and published 325 papers. He was a committee member of more than 55 International Conferences and addressed more than 300 Conferences in 18 different countries. Guillermo received many awards including the Edward Teller Award in 1997; the Archie Harms Award in 1998 and the Marqués de Santa Cruz de Marcenado Award for his outstanding scientific work in the Armed Forces in 2011. In 2007 he was appointed Member of the European Academy of Sciences. Professor Velarde passed away on January 12, 2018 but is always with us inspiring our future endeavors.

Introduction

Technology is the sum of the skills, tools, machines, materials, techniques, and processes used to accomplish a technical goal. Here we present an overview of key technologies necessary to succeed in delivering Inertial Fusion Power to the world.

The chapter is divided into five sections. The first section provides a general introduction to the components of an Inertial Fusion Power Plant (IFPP) based on the deuterium-tritium fuel cycle and goes into some detail about each component. The second section describes key technologies that need to be addressed for a successful IFPP. The third section describes the interrelationships between chamber, driver, and target technologies that provide options for IFPPs. The fourth section describes more of the conventional technologies that are also required for IFPPs. The last section discusses emerging technologies that are expected to make major impacts on IFPP technology: additive manufacturing and artificial intelligence/machine learning.

An IFE Power Plant schematic is shown in Fig. 1. The IFE Driver sends beams of energy in short pulses into the IFE Chamber where they irradiate an IFE Target producing fusion yield. The rate of target irradiation and yield can span from less than one to many times per second. The IFE Targets are produced in the IFE Target Factory. Deuterium and tritium filled capsules are mated with the Target for injection into the Chamber. The Chamber exports heated material to the Electricity Production which converts

Fig. 1 Schematic of an Inertial Fusion Power Plant (IFPP).

this to electricity. Some power is sent to the Driver and Power Plant Operations (the recirculating fraction) while the remaining power goes out onto the Electric Distribution Grid as net power produced.

There are important aspects of implementing ICF into IFPP that impacts technology development. For ICF the fusion reaction is studied on the scale of a cubic centimeter. This means that key physics research moves forward through changes in target design or driver energy delivery. Such improvements could be implemented into a change in targets being manufactured for the IFPP or a change in the details of the beams to target engagement. The activated material and tritium are generally confined to the chamber systems. Also, the total level of residual radioactivity can be kept small for an IFPP due to being able to provide neutron shielding protection of the first wall through careful selection of in-chamber materials. Depending on material selections and the degree of first wall protection, IFPPs may be able to have first walls last an entire plant lifetime. A relatively small amount of tritium is put at risk at any given time for an IFPP since the major tritium concentration is in the target fabrication facility and not in the IFPP Chamber. IFPP Chambers do not require ultra-high vacuum levels to support beam propagation. IFPP may have materials selected having low activation to allow some hands-on maintenance. Finally, IFPPs can separate its driver, chamber, target factory and balance of plant, reducing the risk to any single item.

IFE and MFE share many development issues and both technologies remain aware of dual benefit research. Similar principles are in play for both approaches for fusion energy related to the neutrons released in the fusion process. For example, neutron deposition and tritium production in the breeding blanket of the chamber. The capture of neutron energy in the fluid in the primary thermodynamic cycle of the power plant and at the same time can produce undesirable effects such as activation and materials damage. A major difference however is in considering the first wall which is affected in a very different way in magnetic and inertial fusion designs because of the ability for inertial fusion to protect the first wall.

Key technical challenges for IFE

This section describes especially key technical challenges for the realization of Inertial Fusion Power drawing on the last few decades of ICF and IFE research.

Demonstration of ignition and gain with an affordable driver

The most important next step in implementing Inertial Fusion Energy is for a facility to achieve target ignition and gain. This is important for three fundamental reasons. First, this would prove that the physics of capsule implosion has been proven to be correct. Since the Multi-Mega-joule National Ignition Facility at LLNL is the only present facility in the world with the driver energy to potentially achieve ignition and gain, this is the facility, using its flash-lamped pumped, frequency up-conversion to the ultra-violet (350 nm wavelength) solid-state laser, that is the most likely to demonstrate this first step toward Inertial Fusion Energy with its indirect drive approach. As discussed below, the indirect drive approach uses X-rays produced in a laser heated high Z enclosure (hohlraum) to implode the fusion capsule. Directly illuminated targets, where the fusion capsule is directly illuminated by the laser, are also being explored on the NIF utilizing the irradiation pattern for indirect drive. This “polar drive” configuration has the least impact on facility modifications. The NIF target chamber also has ports for spherical illumination but would require redirecting some of the NIF beams. Physics research over the next decade will motivate more investments in the direct capability on NIF. Second, a demonstration of ignition and gain would also show that the target to achieve this was able to be built and successfully fielded. Given that the target is at cryogenic temperatures and must be built to sub-micron tolerances, this is a significant challenge. This target would then evolve to examine simpler approaches where the “performance cliff” would be understood where ignition and gain is possible and where it is not. Furthermore, the basic physics for other types of targets such as heavy ion targets and direct drive targets would also see important research as the ignition “cliff” for alternative options that may turn out to be more economical would also be studied. Finally, on a single shot basis, some fundamental aspects of emissions of debris, X-rays, and the neutrons could be studied to aid in chamber confinement studies.

Basic inertial confinement fusion target physics

This section describes the basic processes for achieving inertial confinement fusion (ICF) using a suitably formatted driver energy.

In ICF, equal amounts of deuterium (D) and tritium (T) fusion fuel contained in a capsule are compressed and heated to a very high density, temperature and pressure so that the fusion reaction ($D + T \rightarrow n + {}^3\text{He}$) rate is quick enough to cause a significant portion of the fuel to be consumed in these reactions, perhaps as much as one-third, before the capsule is destroyed (Nuckolls et al., 1972; Lindl, 1998). A successful implosion requires fuel pressures of tens to hundreds of Gbars, fusion fuel temperatures of 55 million degrees K, and a density of a few hundred g/cm^3 . In this fusion reaction, 17.6 MeV of energy is released in the form of a 14.1-MeV neutron and a 3.5-MeV alpha particle. The specific energy release from DT is 4×10^{11} J/g. The neutron, with an energy substantially greater than that released by fission by a factor of 5 or more, escapes the high-density burning fuel after depositing a small fraction of its energy. The alpha particles however are stopped and deposit all of their energy and rapidly further heat the fuel. When this occurs, the fusion reaction rate rapidly increases since the rate scales as the square of ion temperature, T_i . To guarantee that the alpha particle is stopped and “bootstraps” the reaction, the thickness $\times$ the density ($\rho \times \Delta R$) must be at least $0.3 \text{ g}/\text{cm}^2$ while the fuel temperature is 5 keV. This is called the Lawson criteria for ICF and is equivalent to the $n \times \tau \times T_i$ for magnetic fusion, where τ is the energy confinement time and n is the particle density. Any driver considered for an IFPP must create these conditions for the capsule. There are five approaches to achieve these conditions: Laser Indirect Drive (LID), Laser Direct Drive (LDD), Heavy Ion Direct Drive (HIDD) and Heavy Ion Indirect Drive (HIID), and Pulse Power Direct Drive (PPDD). These approaches are discussed in the rest of this section along with comments as to their level of progress to achieve IFPP needed conditions in an ICF capsule.

Indirect drive using solid state lasers

A laser driver must compress sufficient energy in space and time and apply it to the IFE target. In LID, the laser energy is first converted into X-rays in a high-Z enclosure, named hohlraum from the German word for cavity, where a near Planckian radiation source with an effective radiation temperature in the resulting plasma of 300 eV is created. The X-ray flux then ablates the outer surface of the capsule. Fig. 2 illustrates the concept of an indirect drive target and also shows the capsule design for 1.8 MJ laser energy deposition. The National Ignition Facility (NIF) is the world’s leading facility for Laser Indirect Drive research. The NIF followed a series of ICF research facilities at LLNL starting with the Argus laser facility in 1976, the Shiva laser facility in 1977, the Nova laser facility in 1985, and the Beamlet facility in 1995. Each facility demonstrated sufficient progress to lead to the next larger laser facility.

The LID approach is the most researched and uses a solid-state laser at 1056 nm that is frequency tripled to 350 nm using potassium di-hydrogen phosphate crystals and used in an indirect drive configuration of three cone angles of beams per side to distribute the energy within the hohlraum. The method of indirect drive is inherently inefficient but was chosen because it was believed to be the lowest risk for successful capsule drive to ignition and gain conditions. The target is a hohlraum with a small 2.2-mm cryogenic capsule filled with D-T at 18 K and surrounded by a low density He gas to prevent the hohlraum wall material from moving in and affecting the capsule implosion. A large number of laser beams (NIF has 192 beams) are carefully placed in such a way that laser spot intensities of order $5\text{--}10 \times 10^{14} \text{ W}/\text{cm}^2$ are produced. Each of these spots are a source of X-rays that then drive the capsule to fusion conditions.

To minimize the driver energy to achieve fusion conditions in the imploded fuel the following physics strategy has been developed. If all of the DT was heated to 5 keV, it would require $\sim 375 \text{ kJ}$ of energy coupled to the fuel since the specific heat of DT is $\sim 100 \text{ MJ}/\text{KeV-gram}$, assuming equal electron and ion temperatures. To put this in perspective, consider that the 1.8 MJ National Ignition Facility (NIF) laser at LLNL at present, with the inefficiencies described above, with laser indirect drive targets, couples only $\sim 10\text{--}20 \text{ kJ}$ to the compressed fuel (hot spot and main fuel) (Soures et al., 1996). The minimum energy required to compress DT occurs when the fuel is in a “Fermi degenerate state.” When the fuel is in this state the pressure is dominated by the degeneracy

Fig. 2 An indirect drive capsule uses a hohlraum to convert laser driver energy to x-rays to drive the capsule (DOE, 1999). On the right the design of the capsule is shown (Campbell, 2020).

Fig. 3 On the left (a), the target and laser temporal profile is shown that produces the fuel conditions shown on the right (b) at stagnation. This shows the ion temperature as function of radius and the density of the imploded DT fuel that has stagnated.

pressure of the electrons, which are fermions—particles with half integer spin obeying Fermi-Dirac statistics. The specific energy required for compression of Fermi degenerate fuel is approximately given by $\epsilon_{\text{Fermi}} (\text{J/g}) \sim 3 \times 10^5 \rho^{2/3}$ (where the units for ρ are g/cm^3). Thus, the energy to compress 750 μg of Fermi degenerate DT to 1000 g/cm^3 , the nominal peak density of the cold but dense fuel is $\sim 1000 \text{ g/cm}^3$, is approximately ~ 22.5 kJ or about 6% of that required to heat an equivalent mass to 5 keV (Sinars et al., 2020; Campbell and Hogan, 1999).

This simple energetics argument explains why the implosion strategy commonly used in the majority of high gain laser driven ICF target designs has been adopted. Recognizing the overall inefficiency in which the energy from ICF laser drivers is coupled to the fusion fuel, in order to maximize the mass of DT that can be imploded and to minimize the size (and cost) of the laser, the implosion dynamics must be chosen to both ignite the fuel and to compress sufficient mass so that significant energy release is possible. A nominal high gain LDD target, pulse shape and fuel density and ion temperature radial profile at stagnation are shown in Fig. 3. For a given target design, this near isobaric imploded fuel assembly is achieved through temporal shaping of the laser pulse. As shown in the figure, the implosion is designed so that a small fraction ($< \sim 5\%$) of the fuel mass is compressed and heated to satisfy the generalized Lawson criteria to ignite and to propagate a fusion “burn wave” into the majority of the fuel, which as described above, must be maintained as close as possible to Fermi degeneracy. Target and driver temporal pulse format are designed so that the partition of the implosion energy between the igniting hot spot and cold fuel is approximately equal. The surrounding cold fuel confines and even tamps the igniting central hot spot and provides the majority of fusion fuel that enables high yield and gain (Sinars et al., 2020; Campbell and Hogan, 1999; Lindl, 1998; Betti and Hurricane, 2016; Miller et al., 2004).

Achieving ignition conditions using the 1.8 MJ NIF laser, where unambiguous alpha particle energy deposition results in a substantial ion temperature increases over that achieved by the laser alone, requires a neutron yield from an irradiated indirect drive target of 250 kJ of neutrons, or 10^{17} neutrons. Until November 2020, the largest yield achieved on NIF was in 2017 when 55 kJ of fusion yield was produced. Recently, however, LLNL achieved a record neutron yield of 100 kJ from a HYBRID-E target shot on November 1 and 100 kJ from an I-raum target shot on November 22. These results are shown in Fig. 4.

The main reasons for the improvement in yield was increasing the X-ray energy coupled to the fuel. Additionally, much improved diagnostics are allowing for improved shell asymmetry measurements, hotspot mix imaging, and measuring fuel configuration at stagnation (Herrman, 2020). These improved diagnostics that enable three dimensional measurements of the imploded fuel configuration will be critical to achieve better target designs and increased fusion performance.

One of the most important attributes of a particular target design for IFPP is its gain—the multiplication of the driver energy times the gain gives the fusion yield of each shot. Multiplying by the repetition rate provides the fusion power for the IFPP. Fusion gains for a specific class of indirect drive targets is given on the right side of Fig. 5.

The DOE is considering increasing the energy of the NIF to try to achieve ignition and gain and to develop robust models of the ignition and gain parameter space for various other options for IFPP including LDD, HIDD, and HIID.

Direct drive using solid state lasers

LDD involves using highly uniform laser beams that each fully engulf the cryogenic fusion capsule as shown in Fig. 6. The driver energy required to create high gain from direct drive can be substantially smaller than that required for indirect drive high gain. The number of beams required for sufficiently uniform illumination is based on the necessary RMS amplitude which has been found to

Fig. 4 NIF Indirect Drive targets achieving record gains in 2017 and 2020 (Herrman, 2020).

Fig. 5 On the right, several target gain curves for indirect and direct drive are shown with varying implosion velocities. A gain of 60 is achieved at 2 MJ. The red dot is a prediction for what is called a fast ignition target. A fast ignition target relies on a special injection of very short pulse duration energy into the target fuel once the target achieves compression. On the left, target gain for laser direct drive is shown in triangles with 300 km/s implosion velocity. A gain of 60 needing less than 1 MJ driver energy would suffice for DD IFE (NRC, IFE, 2013a,b; Lindl, 2003).

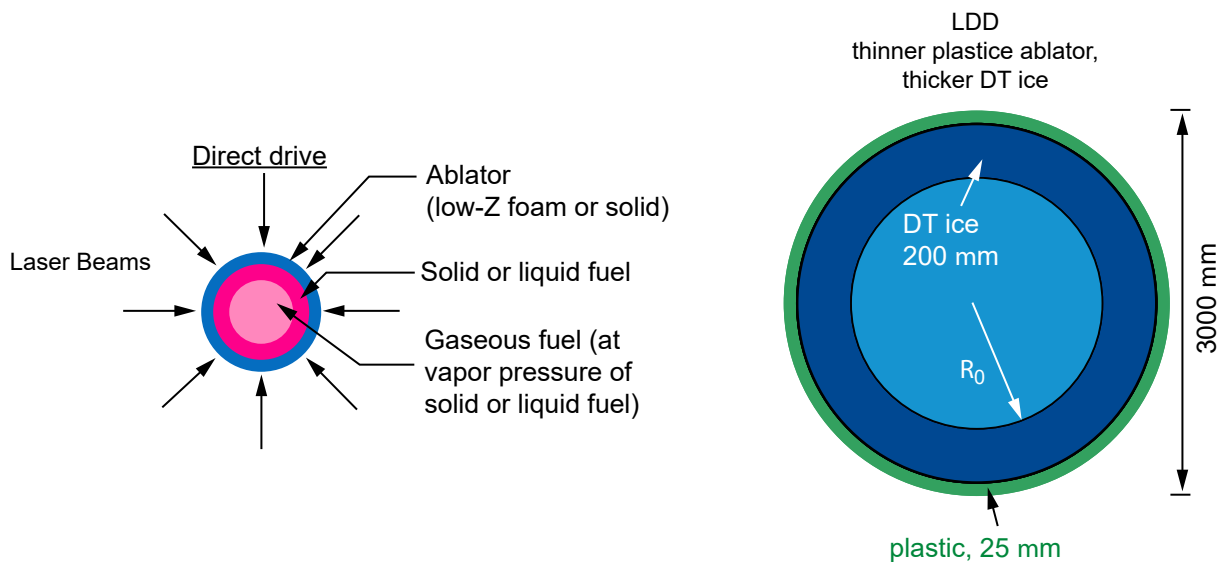

Fig. 6 To the left, the concept for a Direct Drive capsule is shown. (DOE, 1999) On the right is the capsule design that would be driven to gain conditions with a 1.8 MJ laser driver.

Table 1 Quad arrangement by cone angle to shift from indirect to direct drive experimentation on the NIF. A total of 12 quads would need to be re-directed from the 30 and 50 degrees cone angles to the 74.85 degrees cone angle. The NIF chamber has complete symmetry between the upper and lower hemispheres.

Cone	# Ports	Indirect drive layout	Direct drive layout
1	4	23.5°	23.5°
2	4	30°	
3	8	46.5°	46.5°
4	8	50°	
5	12		74.85°

be 0.4–0.6% during the initial to final drive to ignition and gain conditions requiring a focus ratio (beam size to target radius) from less than 1.0–1.8 at the smallest radius.

For LDD, the concentrated laser energy flux generates pressure on the exterior of the target that implodes the fuel to the conditions required for fusion (Betti and Hurricane, 2016). The pressure is produced by the rapid ablation of the outer target surface by a high-intensity laser pulse (see Fig. 6, left side). The peak laser intensity is typically 10^{15} W/cm². The capsule design for a LDD capsule driven by 1.8 MJ of energy to conditions of ignition and gain is shown on the right side of Fig. 6.

The LLE research goal on OMEGA is to achieve the highest possible scaled condition for ignition and to understand degradation mechanisms that limit the implosion performance. This will be done both with spherical illumination for which OMEGA is optimized and then in the polar geometry that exploits the existing illumination geometry of the NIF (Collins et al., 2012). OMEGA energy and power (30 kJ and 30 TW) are insufficient to achieve ignition conditions in the imploded fuel so both simulations and modeling are employed to scale OMEGA results to NIF energies (2.15 MJ and 500 TW). The LDD research on the NIF is focused on laser–target coupling and laser–plasma interaction (LPI) physics in ignition-scale plasmas. Implosions with limited convergence (less than 10), given the present capabilities of the NIF, are also a component of the research. The ability to conduct research over a large range of energy, power and scale size, using both Omega and the NIF, and the modeling and simulation tools developed at the Laboratory for Laser Energetics (LLE) are major positive aspects of LDD research that reduce the risk in scaling from OMEGA to megajoule-class lasers. The goal over the next decade is to develop and demonstrate a convincing physics case for modifying the NIF to enable burning-plasma experiments to be conducted, producing greater than 1 MJ fusion yields from a direct-drive target illuminated in polar geometry (Collins et al., 2012). An additional longer-term goal is to develop a quantitative understanding of LPI physics that limit the parameter space for all laser-driven ICF approaches and to develop and demonstrate advanced laser technology that can expand the parameter space and potentially lead to multi-megajoule yields and high fusion energy gain at MJ-scale laser energies (Campbell, 2020, p. 5).

The NIF was designed and built in such a way that it would be possible to convert the irradiation scheme from indirect drive to direct drive should the decision be made to pursue LDD on the NIF (Tobin et al., 1996). This would involve re-directing 12 quads of beams from the polar angles to around the equator of the NIF chamber. Table 1 shows what the beam layout would be for direct drive experimentation on the NIF. The 12 quads would have re-positioned with six just above the equator of the chamber and six just below to “fill in” the equatorial region of driver beams.

Direct drive gain curves are shown in Fig. 5. This shows that while a 1.8 MJ indirect drive laser target would achieve a gain of about 60 for a fusion gain of 120 MJ, a 1.8 MJ direct drive laser target (such as in Fig. 6) would achieve a gain of about 150 for a fusion gain of 270 MJ.

Direct drive using excimer lasers

It is well known that improved laser-target coupling such as reducing/eliminating electron pre-heat for driving an inertial fusion target and other instabilities is made possible by a shorter wavelength driver. This has generated great interest to examine so-called excimer lasers (more properly called an exciplex laser)—namely the KrF laser which emits at 248 nm and the ArF laser which emits at 193 nm.

The excimer laser was invented by Nikolai Basov et al. at the Lebedev Physical Institute in Moscow (Basov et al., 1970). Exciplex lasers work by having the mixture of noble gas (in this case Kr or Ar) and fluoride absorb energy from an electron beam. The energy causes the noble gas to react with the fluoride producing a temporary atomic “complex” in an excited state (for example, $2\text{Kr} + \text{F}_2 \rightarrow 2\text{KrF}$) that can undergo spontaneous and/or stimulated emission, reducing its energy state back to individual atoms of noble gas and fluoride molecules.

KrF lasers have a very short energy storage time (2 ns) and low saturation intensity (2 MW/cm^2). To extract a useful amount of energy from each amplifier, the pulse length therefore needs to be much longer than the energy storage time. The amplifier is energized by microsecond duration electron beams and to achieve the ~ 10 ns laser pulse required for IFE, angular multiplexing, in which a number of short duration laser pulses, whose temporal format is matched to the IFE target, are amplified and then optically combined has been developed by Naval Research Laboratory scientists to achieve the needed on-target power (Obenschain et al., 2020).

Fig. 7 One-dimensional hydrocode simulations of target energy gains as a function of laser energy for conventional direct drive targets. The simulations employed zooming of the laser focal diameter (Obenschain et al., 2020, p. 5).

A KrF laser for an IFE power plant has a number of potential advantages over a Nd-solid state laser: (1) the shorter wavelength reduces laser-plasma instabilities and maximizes absorption and ablation pressure; (2) electron beams can easily operate at a high pulse rate; (3) a KrF laser on target intensity can be made very uniform using the technique of induced spatial incoherence with many overlapped beams and (4) and since the far field image as the beam leaves the amplifier is projected onto the target, it is possible to “zoom” the beam as the direct drive target implodes such that an ever-smaller diameter beam continues to drive the compression significantly reducing the laser energy required (Obenschain et al., 2020). The overall laser efficiency of KrF, however, is only about 7% such that higher gain targets (e.g. gain of 140) is required for IFE economics compared to, for example, solid state lasers (e.g. gain of 60 at 16% efficiency).

Recent studies indicate that an ArF laser (193 nm) may have substantial advantages over a KrF laser (248 nm). At the shorter ArF wavelength the following are achieved; the greatest pressure, the highest ablation rate, the lowest electron temperature, the lowest susceptibility to laser plasma interactions (LPI), and the highest bandwidth (10) which should avoid cross beam energy transfer (CBET) (Obenschain et al., 2020).

Fig. 7 shows how these benefits aid in the gain of direct drive targets comparing ArF, KrF, and solid-state Nd where the frequency has been tripled to 351 nm in one-dimensional hydrocode simulations. For example, while tripled Nd glass would achieve again of 75 at 1 MJ laser energy, KrF would achieve a gain of 150 and ArF a gain of 175. This shows that the ArF option, with the lowest driver energy for the same modest net electrical power, may be the least expensive and also the lowest risk option for a IFPP using an excimer laser.

While the benefits of KrF and ArF have been more established in recent years, there is no current plan for excimer laser research to be expanded at this time. These comparisons need much more peer review to establish excimer lasers as a potential viable candidate for IFE. It is expected that the achievement of ignition and gain on the NIF will provide more key confirming data as to the possible role of this driver technology for IFPP.

Indirect drive using heavy ion beams

As early as 1980 the proposal to use heavy ions (HI) to illuminate an ICF target and produce an efficient implosion fuel burning with high gains using DT fuel was considered. From 1981 to 1985 along with the design of the HIBALL I-II power plant (Böhne et al., 1982) a significant number of other power plant studies can be found in the literature: HIBLIC-I (Yamaki et al., 1985), HYLIFE I-II (Moir et al., 1994), OSIRIS (Meier et al., 1992), and HIDIF (Hofmann and Plass, 1998).

One key seminal scientist in proposing Heavy Ion Fusion, Al Maschke (Martin, 1996) started by proposing research in high-energy proton synchrotrons early in the 1960s. Later it was understood that the range of those protons in a fusion target was too long and so Maschke switched to heavy ions of energy about 100 MeV/u that have shorter range and had the possibility to design efficient drivers exploiting traditional linear accelerators. An advantage of HIF is that the coupling of the driver energy does not involve the excitation of plasma instabilities which remains a major issue with all laser approaches that presently limits the laser-target parameter space for achieving high fusion gain.

The mechanisms for target implosions are essentially the same as in the case of lasers but different when considering the energy deposition in the target as seen in Fig. 8. The interaction of heavy ions with matter (ablation of target materials) is quite well understood, guided by Coulomb interaction with screening effects due to the plasma conditions of the matter during its interaction. Mehlhorn explains how to incorporate “finite temperature effects by scaling the relevant bound electron parameters with the degree of material ionization as well as by including the free-electron stopping power. In this article he discusses both the phenomenon of range shortening and range lengthening in heated material. The calculations indicate that the minimum ion range in heated

Fig. 8 Heavy ion beam indirect drive target; ion beams shine on the radiation convertor; X-rays from the radiation convertors fill the inside of the hohlraum and heat the capsule (DOE, 1999).

material is approximately one-half that in cold dense targets, independent of the identities of the projectile ion and the host material" (Mehlhorn, 1981). The ions effectively deposit all of their energy in the plasma and the penetration of the ions at the relevant energies, charge, and mass is in the range of hundreds of microns (Kothe et al., 1990).

For the direct drive approach, we can compare a heavy ion driver and laser driver from the point of view of coupling energy to the target that is the efficiency in which incident driver energy is converted into kinetic energy of the imploding target. Heavy ions can have a total efficiency up to 25–30% while lasers will be in the range (at best) of 8–10%.

If we indirect drive for target implosion for HIF and consider the losses occurring in the conversion of laser energy to X-rays in the case of the hohlraum target and the coupling of X-ray energy to the capsule which depends on the area ratio of the hohlraum to the capsule, the integral efficiency will be $\sim 2\text{--}4\%$. This low efficiency motivates the option of Heavy Ion Direct Drive. It is true that the number of beams is limited for Heavy Ions because of the architecture of final focusing of accelerators and the potential hydrodynamic instabilities created by a non-uniform illumination that can destroy the appropriate implosion efficiency limiting target gain. Low mode non-uniformities can also result in the inefficiency of converting the implosion kinetic energy into pressure at the fuel stagnation. As discussed earlier, for an acceptable recirculating energy fraction, economics suggests that a value of driver efficiency multiplied by the target gain should be around 10. For a heavy ion driver efficiency in the 30–40% range, this suggests the heavy ion fusion target gain need only be 30–40.

Research in Heavy Ion Fusion has been experimentally devoted to the area of accelerator technology, and very little to target implosion studies or associated physics except basic research in High Energy Density Physics (HEDP) and interactions in order to achieve the magnitudes required for the power plant application. The most explored case for considering heavy ions as the driver for an ignition facility is the case of the European Heavy Ion Driven Inertial Fusion Facility (HIDIF) but laser facilities such as the National Ignition Facility (NIF) are more adequate for this step and heavy ions are better considered for a power plant (Hofmann and Plass, 1998).

Of the two techniques to build heavy ion accelerators the induction linac is favored today over the radio-frequency technique due to high peak currents possible and proven reliability and efficiency as well as being able to achieve short pulses and support multiple beams.

Different types of heavy ion targets have been proposed since the 1980s and 1990s. Because of the large effort in X-ray driven targets and the common capsule hydrodynamics indirectly driven ion targets have received the most attention as shown in Fig. 9 (Callahan-Miller et al., 1999; Tabak et al., 1998; Basko and Meyer-ter-Vehn, 1993).

Standard hohlraum-to-capsule radius ratio design (HCR – 2.1) Gain 60 @ 6 MJ

Hohlraum is smaller – requires smaller beam spots

Fig. 9 Two heavy-ion fusion indirect drive target designs have evolved (references in figure).

Fig. 10 Gain curves for distributed radiator targets. The lower set of curves is for the conventional case-to-capsule ratio while the upper set is for the close-coupled design. For each set, the solid curve is 250 eV drive and fixed ion range, the dashed curve is 250 eV drive and varying ion drive, and the dotted curve is 240 eV drive and fixed ion range, and the dot-dash curve is 240 eV drive and varying ion range. The squares represent the three integrated LASNEX calculation point designs (Callahan-Miller and Tabak, 2000, p. 2083).

Full study of these targets, both two-sided radiator and distributed radiator, consider a driver energy range of 4–10 MJ and Pb + ions from 3 to 10 GeV. As discussed by Callahan-Miller and Tabak, for the original distributed-radiator-target, it was assumed that all the ion current was carried by only two beams, one on each side, with “top hat” beam density distributions. Quadrupoles cannot focus 3 MJ of ion beam energy in a single beam. Since more than two beams are then needed, all of the beams need to enter the hohlraum at an angle relative to the hohlraum centerline axis to allow sufficient space for final focusing magnets. Chamber calculations also show that a top hat density distribution is not realistic for conventional ballistic chamber transport. The beam distribution was important originally in the distributed radiator target because the central region of the hohlraum was a beam block. For a top hat distribution, 25% of the beam energy hit this beam block but was wasted. With a Gaussian distribution, 50–55% of the beam energy would hit the beam block. If two Gaussian beams were used, the energy required to drive the original target design would therefore increase from 6.5 MJ to more than 10 MJ (Callahan-Miller and Tabak, 1999, pp. 1–2).

In Fig. 10, the gains are shown for these designs. The baseline design allows large heavy ion beam spot sizes but requires more driver energy to achieve a gain of 55 for 6.7 MJ of beam energy. The close coupled design requires smaller ion beam focal spots but produces more than adequate gain at low driver energy giving a gain 130 from 3.3 MJ of beam energy. To achieve closely coupled results, the hohlraum dimensions were reduced by 27% while driving the same capsule. This reduced the beam energy required to 3.27 MJ. This close coupled target can also be scaled down for an Engineering Test Facility. LASNEX calculations predict a gain of 94 can be achieved from 1.75 MJ of beam energy (Callahan-Miller and Tabak, 2001, 1998).

One reason for significant improvement over prior gain curves 20 years earlier is the fact that now instead of 12 beams each delivering 417 kJ in 100 ns for 5 MJ total energy and for a gain of 87, 120 beams were now delivering nearly 7 MJ of energy using six different pulse durations and two different ion energies (3.3 and 4 GeV) for a gain of 55. This is shown in Fig. 11.

The national USDOE strategy that was developed in the last decade was to achieve ignition and yield on the NIF and then to conduct research evaluating heavy ion indirect drive targets from which to select the optimum development path for the heavy ion accelerator. The lack of ignition to date on NIF has reduced the urgency and motivation for a robust HIF effort. However, the Neutralized Drift Compression Experiment II (NDCX-II) at Lawrence Berkeley Laboratory was completed and is conducting research relevant to HI IFE by heating targets to eV conditions for the study of warm dark matter. The experiments in High Energy Density Physics in SIS-18 at GSI Darmstadt (Germany) and those at ITEP (Russia) also have been relevant for Heavy Ion Fusion (Hofmann, 2018).

High intensity heavy ion accelerators are being developed for nuclear structure and other areas of research—namely the FAIR facility at GSI in Germany (Schoenberg et al., 2020), the Relativistic Heavy Ion Collider at Brookhaven National Laboratory in the United States (Ozaki and Roser, 2015), and the HIAF in Lanzhou, China (Zhao et al., 2014). These developments will benefit future HIF programs by advancing accelerator technology and resolving issues such as activation of the accelerator structure by uncontrolled heavy ion beam loss and “loss-induced” degradation of the vacuum by gas desorption (Hofmann, 2018).

Direct drive using heavy ion beams

While as mentioned above heavy ion beam drivers have been primarily associated with indirect drive, there has also been limited consideration for direct drive concepts. In any target design, it is theoretically well known that the most efficient implosions would

Block	No. of Beams	Power, TW	Pulse width, ns	Energy, MJ
A (foot)	16	70	6.5	0.46
B (foot)	16	20	38.3	0.77
C (foot)	16	53	10.1	0.54
D (main)	24	120	13.7	1.64
E (main)	48	388	9.3	3.61

Fig. 11 Heavy Ion Beam timing and energies for the Robust Point Design-2002 IFE Power Plant (Yu et al., 2003, p. 2).

be done at the peak of rocket efficiency with a low-Z ablator having small ionization energy. For heavy-ion direct-drive target coupling efficiency, there are two areas that may be improved upon according to recent investigations: first, decoupling the ion-beam deposition away from the ablation front during the implosion; and second, beam deposition non-uniformity and resulting RT instability (Logan et al., 2008).

As shown in Fig. 12, LASNEX calculations indicate that for this direct drive target and heavy ion beam pulse target coupling efficiency in direct drive is 16% with a CH:DT ablator, and 18% for a pure DT ablator. These impressive results are the highest overall coupling efficiencies published for 1-D heavy ion capsule implosion calculations that ignite with a total beam input energy of only 1 MJ. The resulting implosion velocity (4.45×10^7 cm/s) is higher than the minimum needed for ignition (3.68×10^7 cm/s). In the future, we will consider driving low-Z NIF-size capsules with heavy ion beams assuming we can focus heavy-ion beams to 1 mm radius spot size, with heavier krypton ions for the lower ranges required, and with short-focal-length copper final-focus magnets. If successful designs emerge along with NIF achieving ignition, the prospects for heavy-ion fusion development would look more promising since it would suggest a gain of 100 at just 200 kJ total drive energy. Further if we can optimize coupling efficiencies to 25% for larger mass targets, then igniting large fuel assembly energies with 1 MJ might be possible with 4 MJ of beam drive energy. Such large fuel assemblies with T-lean fuel (Tabak, 1996; Atzeni and Ciampi, 1997) (DD fuel with a small inner DT spark-plug) at compressed $\rho \sim 10$ g/cm³ would self-breed tritium without external blankets, and internally capture the neutron energy into mostly plasma energy for direct conversion. These would create great interest in heavy ion fusion (Logan, Perkins, and Barnard, 2008, p. 5).

Fig. 12 A "pie" diagram of the target construction for the LASNEX calculation (a), and the 50 MeV argon ion-beam power pulse shape used (b). This case gives a fusion gain of 50 for 1 MJ of beam drive, assuming the incident beam profile zooms in a factor of 2 in radius (from 2 to 1 mm) during the drive.

If ignition and gain are achieved on NIF then motivation for further studies and research of DD-HIIF would certainly grow.

Direct drive using pulse power inertial fusion

The main approach to producing ignition and gain using pulsed power is Magnetized Liner Inertial Fusion (MagLIF). In this approach pulsed-power-driven IFE would utilize ≥ 50 MA of current from a pulsed power accelerator to generate sufficiently high magnetic field pressures to compress and heat magnetized, pre-heated fusion fuel contained in a cylindrical target to ignition conditions. The laser energy needed for preheating the fuel is only about 50 kJ. An external magnetic field of ~ 100 kG is also used to insulate the fuel as it is imploded. The magnetic Reynolds number is large trapping the internal B field so that it is significantly increased to > 10 MG. This field significantly reduced radial heat conduction and can trap the 3.5 MeV alpha particles that then deposit their energy and ignite the DT fusion fuel. The pulsed-power approach has relatively low-cost and high-efficiency driver technology that appears to be scalable in a straightforward way to the peak power and total energy presently estimated to be needed for IFE (National Research Council, 2013a,b). Experiments on the NIF to explore laser heating and other integral experiments using laser compression rather than magnetic pressure for the MagLIF program are ongoing (Barnak et al., 2016).

The primary conceptual approach to achieving pulsed-power IFE, Magnetized Liner Inertial Fusion (MagLIF), is a direct-drive approach—that is, fuel compression and subsequent heating (laser heating is used to preheat the fuel) are driven directly by magnetic pressure. This approach offers the potential benefits of a relatively simple cylindrical target geometry and highly efficient delivery of driver energy to fuel implosion and heating. However, there is considerable uncertainty (i.e., technical risk) surrounding all aspects of this approach owing to a limited experimental data on target physics and ignition and a lack of in-depth design studies on inertial fusion reactors at the proposed multi-GJ yield and ~ 0.1 Hz repetition rate called for by advocates. In addition to MagLIF, there are other promising approaches to pulsed power fusion energy, including one called magnetized target fusion (MTF). While MagLIF operates on the 100-ns timescale, is ~ 1 cm in size, and involves open magnetic field lines, MTF operates on a ~ 1 μ s timescale, is tens of centimeters in size, and involves closed (field-reversed) magnetic field lines. A pulsed-power fusion reactor system would be very different from both laser and heavy-ion fusion systems. As such, the technological or economic failure modes are likely to be very different (National Research Council, 2013a,b).

Since 2018, simulation and experiments at the Z facility at Sandia produced 1 kJ of DT fusion yield using 21 MA of current to produce a 15 T magnetic field where results agreed with LASNEX 2-D predictions. Sandia's goal is to demonstrate 2 kJ and 4 kJ DT fusion yields using 20 T and 25 T magnetic fields generated by 20–21 MA of current by 2022 (Sinars, 2020).

Direct drive pulsed power inertial fusion remains a viable candidate for future IFPPs. In addition to the physics challenges, the driver, unlike lasers, must be physically connected to the fusion target. Concepts such as the “recycling transmission line” or RTL have been developed but significant engineering and operational challenges remain.

IFE chamber technology

The chamber of an IFPP that confines the fusion target yields has an advantage over most magnetic fusion concepts in that a “first wall” (first surface that target emissions make contact with) can be a replenishable material or perhaps a material that can be easily periodically replaced. This opens up the design space to allow a greater range of options for the structural wall that holds vacuum and confines the repeated fusion yield. Along with this advantage, however, comes a key difference between the magnetic fusion neutron loading and the inertial fusion neutron loading of chamber components.

Inertial Confinement Fusion has had a very large number of proposals for the design of Power Plants since the early 1970s. More recently proposals include: LIFE (Latkowski et al., 2011), HiPER (Perlado et al., 2011), KOYO-F (Norimatsu et al., 2009), FALCON (Ogawa et al., 2008), and a large effort in the United States due to the High Average Power Laser (HAPL) and the ARIES initiatives (see <http://aries.ucsd.edu/ARIES/>).

The chamber of an IFPP is the location of the implosion-ignition-burnup of the ICF target at its center. The chamber could be filled with a protecting gas at a low density such as 5 $\mu\text{g}/\text{cm}^3$ or alternatively be designed to be at a much lower ~ 1 μTorr vacuum. The first surface of the chamber wall (the so-called First Wall) receives the radiation in the form of target ions, X-rays and neutrons. The chamber must also host the system to extract the neutron energy as heat and at the same time support materials to cause tritium to be produced which is called “breeding” tritium.

The degrading effects of X-ray radiation and target debris ions can be mitigated or eliminated through the use of liquid layers adhered to the first wall or by a chamber gas to absorb these target emissions. For examples, the LIFE IFPP employs Xe gas, the HIBALL and KOYO IPFFs employ thin liquid layers, while the HYLIFE-II IPFF uses a thick liquid layer. These are in contrast to non-protected first wall chambers such as HiPER.

We now describe in more detail, as examples of alternative chamber technologies, the IFPP chamber technologies for the HiPER concept (Juarez et al., 2013), the LIFE concept (Latkowski et al., 2011), the HYLIFE-II concept (Moir et al., 1994) and the KOYO-F concept (Norimatsu et al., 2009).

The HiPER concept employs a dry First Wall (FW) made of 1-cm of Ferritic-Martensitic Steel (EUROFER97) with a 1-mm coating of nanostructured W. The liquid metal $\text{Li}_{17}\text{Pb}_{83}$ is the coolant. The breeding blanket is also made of EUROFER97 and also with $\text{Li}_{17}\text{Pb}_{83}$ circulating inside. The HiPER concept also calls for a second heat removal system using He to remove heat from the FW while maintaining $\text{Li}_{17}\text{Pb}_{83}$ in the main blanket. There are two heat removal approaches using the Self-cooled Lithium Lead (SCLL) concepts. One fully integrates the He and SCLL into the Integrated First Wall Blanket (IFWB) while the other keeps these two systems separate in the Separated First Wall Blanket (SFWB) arrangement, as shown in Fig. 4.

Fig. 13 In the HiPER concept, both an Integrated First Wall Blanket and a Separated First Wall Blanket arrangement is under consideration (Manas, 2013). The chamber has 48 beam ports to support the Direct Drive approach.

The chamber structure is made up of two hemispheres with an internal radius of 6.5 m with each hemisphere composed of eight sections as shown in Fig. 13. The chamber has 48 laser beam penetrations each 40 cm in diameter. As shown in Fig. 4, each blanket module has a thin 8-cm layer of LiPb coolant closest to the chamber which flows in cool $\text{Li}_{17}\text{Pb}_{83}$ leaving from the heat exchangers. Just behind this layer there is a second layer 42 cm thick that flows out of the chamber to the heat exchangers. Together these $\text{Li}_{17}\text{Pb}_{83}$ coolant flows not only remove neutron heating but ensures a tritium breeding ratio (TBR) of at least 1.10. In a study to select a thin (42 cm) or thick (67 cm) layer for the second layer of the blanket, the thinner option was chosen to reduce weight and hazardous nuclide production. However, this also results in the need to enrich the Li^6 concentration to about 35% in the blanket and increase the shielding protection for the vacuum vessel by adding graphite shield behind the blanket enlarging the overall structure (Juarez, 2013). Pure Li was avoided as a coolant to reduce the safety risk.

The LIFE chamber was also designed in a modular fashion and constructed from eight identical sections as shown in Fig. 14 below, configured into a sphere with a radius of 3.4 m. Inside each section, in the region nearest the chamber center, there are rows of 10-cm diameter steel tubes through which flow the liquid lithium, the selected coolant for the FW. The coolant carries away the heat from neutron deposition and from the ions and X-rays not absorbed by the chamber FW Xe gas protection. The flow is very rapid through the pipes and they create a “skin cooling” effect. This is shown in the left side of Fig. 14. The coolant then is turned around at the bottom of the blanket and then flows up the through the bulk of the section, the breeding blanket region, at a much slower speed. It is here the main tritium breeding occurs.

The coolant enters into the LIFE first wall coolant tubes at a temperature of 550 °C and arrives at bottom of each section where it turns to enter the blanket region at 600 °C. It is further heated during its pass in the bulk of the blanket with a design exit point of 800 °C. Steel has a limit of 600 °C and so insulating panels of W must be used to allow the lithium to rise to its maximum design temperature. Refractory coatings such as W are compatible to 1300 °C. A total of 48 penetrations for lasers go through the chamber wall system comprising a 3% solid angle. Notably, there are no beam tubes attached to the chamber system since an exterior wall outside the chamber region is the vacuum barrier.

The KOYO-F IFPP concept (Norimatsu et al., 2009) is representative of the thin protection or wetted FW design options similar to the HIBALL (Badger et al., 1981) and Prometheus-L (Waganer et al., 1992) IFPP concepts. The main idea is to have FW structures where a thin sacrificial layer is formed on its face thick enough to absorb the X-ray and debris/ion target emissions and be able to be replenished before the next shot. The KOYO-F IFPP concept uses $\text{Li}_{17}\text{Pb}_{83}$ as this sacrificial layer on the first wall.

The KOYO concept employs an unusual technique to protect the ferritic steel first wall with this wetted surface. The chamber first wall is formed by a structure of integrated panels formed into boxes that allow the hot liquid $\text{Li}_{17}\text{Pb}_{83}$ to flow from the top of the chamber toward the bottom in a cascade of flows where the overflow of certain boxes spills out and coats the first surface. The lower the cascade falls in the chamber the wider the structure necessarily becomes to ensure continuous and uniform coating. The maximum diameter of the chamber is 3 m but is reduced from the top to the bottom of the chamber by the overall thickness of the cascade structure. Fig. 15 shows these details. The top of the chamber is formed in a conical shape that studies show will result

Fig. 14 (Left) The LIFE first wall is composed of steel tubes that are mounted to coolant plena on the sides of the blanket. (Center) The LIFE chamber consists of eight identical modules assembled into sections for transport to the engine bay. (Right) The LIFE blanket utilizes skin cooling to maintain structural material strength and corrosion resistance (Latkowski et al., 2011).

Fig. 15 (Left) Cross section of the 3-m diameter chamber shows the cascade structure thickening from the top to the bottom. (Center) Two views of the details of the cascade structure shows the interior flow of $\text{Li}_{17}\text{Pb}_{83}$ to and how the exterior surface is coated to 5-mm thickness. The height of each cascade small module is 30 cm that correspond to 0.25 s synchronized with the chamber repetition rate of 4 Hz. (Upper Right) Top chamber view shows the irregular pattern the cascade structure makes (Norimatsu et al., 2009).

in a layer of condensed $\text{Li}_{17}\text{Pb}_{83}$ to coat this surface as well. KOYO is designed to contain 300 MJ yields at a rate of 4 Hz in four separate chambers supported by a single driver (Norimatsu et al., 2009).

The IFPP concept HYLIFE-II is a thick FW protection scheme. This IFPP uses a material called FLiBe (Li_2BeF_4) as a coolant. This FLiBe is a molten salt that is a 2:1 combination of LiF and BeF_2 with a melting point of 459 °C. In this concept, liquid FLiBe coolant is formed in stable jets using nozzles in the top of the chamber that taken together provide a thick shield for the chamber FW yet still allow driver beam access and target injection to the chamber center. In Fig. 16, there is an image of molten FLiBe flowing and it a completely clear liquid when melted. The flowing FLiBe in the chamber also absorbs all X-rays and ionic debris emitted from

Fig. 16 Molten FLiBe flowing in a tube while being heated. This sample has a slightly green tint due to entrained uranium tetrafluoride.

the target as well as most of the neutron energy and therefore acts as the coolant in addition to protecting the first wall. The FLiBe also breeds the tritium in the chamber. Studies show that rapid enough condensation occurs to support shot rates exceeding 5 Hz in the presence of single 1 GJ fusion yields (Moir et al., 1992).

Fig. 17 shows pulsed flows and oscillating jets flows. Pulsed flow is used in the center region to create a slug of the FLiBe coolant. The role of this slug is to clear the beam and target injection path from the splash generated from the prior shot. The slug is created every 1/6th to 1/8th second and flows downward in a height of 1-m and about 60 cm by 60 cm on a side with a speed of 12–16 m/s. The oscillating jets are generated by nozzles oscillating at 8 Hz to support high chamber repetition rates. The oscillating jets are a neutronically relevant 70-cm thick. All working together this creates a pocket designed to let targets and beams be injected to the center of the chamber to create the micro-explosion and the FLiBe jets shield the components and also clear the chamber between shots, all the while producing tritium and generating electricity.

From an economics point of view, it is very desirable for the FW of a IFPP to last the plant lifetime. The lifetime of the first wall depends on the type of protection and design of the first wall. Research focused on ion-induced damage to the first wall for direct drive target ion emissions suggests that the first millimeter of the first wall will be severely damaged and need replacing within days of full power operation if there is not a protective gas, a wetted wall, or thick interior flowing solid or liquid blanket to attenuate the ions (Gonzalez-Arrabal et al., 2020). In a dry direct drive chamber where there is no protection for the first wall the key damage to the first wall and the limiting lifetime factor is ion bombardment that in a fairly short time embrittles the W coating protecting the steel (Garoz et al., 2016). The extent and rate of the damage depends on the pulse conditions such as yield, duration, repetition rate, and whether the surface experiences a thermal load (X-ray loading) concurrent with the pulse. Direct Drive/Dry-Non-Protected Wall studies (Gonzalez-Arrabal, 2020) indicate that the lifetime of the coarse-grained W protective FW layer in the presence of ion and X-ray exposure is: for 20 MJ per shot only 1000 shots; for 50 MJ/shot at 1 Hz only minutes; and at 150 MJ/shot at 10 Hz only seconds.

Studies have examined the use of nanostructured materials to be used (Andrievski and Khatchoyan, 2016) in extreme conditions and, in particular, columnar nanostructured W was proposed to replace coarse grained W as the protective 1-mm coating for the EUROFER97 FW (Gonzalez-Arrabal et al., 2014). A nanostructured material is where the grain size is on the nanometer scale size. There appears to be some resistance in nanostructured material to radiation effects as well as an increase in yield strength and lower ductile-to-brittle transition temperature (Zhang et al., 2009). The main aim of nano-structuring is to create a large density of Grain Boundaries (GBs), which will promote self-healing and delay blistering by increasing the effective area where light ions can be accommodated or by creating effective diffusion channels that allow the light species to escape. More research is needed to know the influence of the GBs in the transport of light species such as H or He. Migration energies of light species in GBs under realistic operational conditions need to be well understood since the retention of light species in GBs makes nanostructured materials useless for FW protection applications (Padmanabhan, 2001).

Engineered surfaces such as needles and foams may also offer a solution. Implementing an engineered surface greatly increases the surface area upon which the ions will be depositing. This reduces the concentration and delays the onset of effects. Experiments exposing samples to ion bombardment performed on needle-like carbon fibers covering a W layer showed that neither the fibers nor the W were damaged (Renk et al., 2012).

The use of W-hollow nanospheres (W-hNPs) has also been proposed for W protection over the FW of a direct drive IFPP chamber. Using molecular dynamic and object kinetic Monte Carlo simulations, it was shown that W-hNPs are able to withstand very high temperatures (~ 3000 K) and very large internal pressures (> 5 GPa at this temperature) before rupturing. Even more interestingly, a nominal pressure increase as for an ICF exposure stimulates openings in the material that allow trapped gas to be released but then close within a few nanoseconds. Also, defects within the W-hNP shell migrate to surfaces at the operating temperatures

Fig. 17 (Left) HYLIFE-II pulsed flow. The flow speed for 8 Hz (chamber repetition rate) is 16 m/s with a 2-m fall height giving a flow rate of 34 m³/s. (Center) HYLIFE-II oscillating flow. (Right) Thick horizontal and vertical liquid jets protect the beam ports from radiation and help clear splash liquid for the next shot (Moir et al., 1992).

experienced and then annihilate. Long term integrity of such materials under long term irradiation remains a concern (Díaz-Rodríguez et al., 2020).

The behavior of helium in the thin tungsten layer protecting the FW in an unprotected chamber scheme is a key issue. If He builds-up due to both transmutation (n, α) reactions or direct penetration into the FW of He burn products from the ICF target burning, this degrades the metal. If He escapes regularly and avoids build-up the life of the tungsten layer would be extended. One mechanism for escaping would be if the He atoms diffuse out of the metal due to the elevated temperatures of the W. It is also important to understand if pulsed impingement (as for ICF) has any difference from continuous impingement (as for MFE). To explore this, Object Kinetic Monte Carlo code calculations were performed to evaluate the difference between continuous and pulsed He irradiation of W (Rivera et al., 2013). These results are shown in Fig. 18 and show that at temperatures over 1300 K, pulsed irradiation leads to larger He retention and creates a much higher density of vacancies that are highly occupied by He atoms compared to continuous irradiation under the same conditions (ion energy, temperature, and fluence). These results account for the decrease in the W damage threshold experimentally observed.

In depth the limiting damage for the blanket structure will be due to neutrons. The duration of the neutron pulse that is released from an ICF target is so short that it can be assumed to be released in a step function or instantaneously. There is neutron scattering that takes place in the fuel region such that the 14.1 MeV neutrons share energy with alpha particles and unburned deuterium and tritium, and this results in a spread of neutron energies that peaks at 14.1 MeV. The average neutron energy leaving the capsule is about 12 MeV. This neutron takes about 50 ns to arrive to a 5-m radius chamber wall. With a spread in neutron energies of 2 MeV, the neutron pulse (FWHM) is about 100 ns in duration. Therefore, for an IFE power plant operating at 1 Hz, 1 GJ yield and a chamber radius of 5 m, the first wall would experience a neutron fluence of about $1\text{E}14 \text{ n/cm}^2$ —but a neutron flux of about $1 \times 10^{21} \text{ n/cm}^2/\text{s}$ —an extremely high value. The areal atomic density of iron—the major constituent of steel is $8.5 \times 10^{22} \text{ atoms/cm}^2$ per cm thickness so that in a year with an IFPP at 80% availability the $2.5 \times 10^{21} \text{ n/cm}^2$ neutrons will have collided with 3% of the atoms in the chamber wall. This also means that the first wall for an IFE power plant under these conditions would experience a year's worth of neutron damage during a year's worth of power operation, but this damage will be accumulated over a total irradiation period of 250 milliseconds. So, there are therefore very different damage rates for IFE and for MFE.

Fig. 18 (a)–(c) Ratio of He retained to total implanted He for W samples irradiated with He at 3 keV under different conditions: (a) Continuous irradiation at a dose rate of $2 \times 10^{12} \text{ ions/cm}^2\text{-s}$. (b) Pulsed irradiation, with $2 \times 10^{12} \text{ ions/cm}^2$ per pulse at a repetition rate of 1 Hz. (c) Comparison of continuous and pulsed irradiation at 1300 K and for different fluxes. In all cases, the number of He ions per cm^2 averaged over 1 s is the same for $2 \times 10^{12} \text{ ions/cm}^2$ or $2 \times 10^{13} \text{ ions/cm}^2$. (d)–(f) Fraction of He retained in trapping sites for W samples irradiated with He at 3 keV under different conditions. (d) Pulsed irradiation at 700 K, with $2 \times 10^{13} \text{ ions/cm}^2$ per pulse at a repetition rate of 1 Hz. (e) Pulsed irradiation at 1300 K, with $2 \times 10^{13} \text{ ions/cm}^2$ per pulse at a repetition rate of 1 Hz. (f) Continuous irradiation at a dose rate of $2 \times 10^{13} \text{ ions/cm}^2\text{-s}$ (Rivera et al., 2013).

Further, “a recent review of pulsed damage effects...concluded that there is sufficient experimental and theoretical evidence to be concerned about this phenomenon. Pulsing effects on precipitate phase stability and large changes in swelling and interstitial loops have been observed in stainless steel. Large changes in the void microstructure in Ni irradiated under pulsed conditions have also been observed. While there is no experimental evidence with a high neutron fluence at damage rates shown in Figure 8 it should be clear that ... the damage produced by 1 MW y/m² exposure of metal under steady state conditions may bear no resemblance to 1 MW y/m² applied in a [IFE-like] pulsed mode” (Sawan, 2011, p. 448).

Fig. 19 shows the instantaneous damage rates in a SiC first wall. “Furthermore, the pulsed nature of IFE results in extremely high instantaneous damage production rates as high as 40 dpa/s. The ratio of instantaneous-to-average dpa rate is about 50 million, with implications to the accumulation of surviving defects. In addition, the time spread of displacement damage production is longer than that for helium production leading to peak instantaneous He/dpa ratio that is higher than the average value. The strong directional bonding and the mass difference between Si and C atoms result in unique displacement features in SiC as compared to metals. The useful lifetime of SiC/SiC composites in a fusion neutron environment depends on the magnitude of swelling and the overall impact of the transmutation products on strength that are not presently understood. As facilities are not currently available to experimentally simulate the fusion neutron environment, active modeling and experimental activities in this area will provide significant insight into the physics of damage production and accumulation in SiC/SiC composites” (Sawan, 2011, p. 449).

The conditions of a first wall due to neutron damage at the end of a single year in a Magnetic Fusion Power Plant where a continuous flux of 4.5×10^{14} neutrons/cm²/s is impinging the first wall will be quite different than for an Inertial Fusion Power Plant unshielded first wall damage where, for the same neutron loading, the total irradiation time is less than 1 s and the wall has been annealing for the remainder of that second. For each single 100 ns pulse of neutrons striking the first wall, there is an annealing time of nearly a full second until the next 100 ns pulse arrives. Analyses using molecular dynamics simulations can provide insight into these very different irradiation conditions to gain some understanding of the outcome but have yet to be done. These would have to be validated with experiments in a facility that also does not exist yet. Prudence may suggest assuming materials will not stand up well to this very irregular neutron irradiation and take every possible step to reduce the neutron loading of the first wall in developing IFE power plant concepts. This suggests that a material that is continuously replenished and about a half to a full meter in thickness be placed between the first wall and the burning target. IFE concepts that employ liquid FLiBe or lithium or solid LiO₂ granules would reduce this pulse and create a more benign first wall outcome. The instantaneous concentration of both helium and hydrogen atoms in the first wall will also be much greater than for MFE. It is unclear how the combination of large dpa rates, helium production, and hydrogen build up inside the first wall will affect the first wall material lifetime.

Fig. 19 Instantaneous damage rate in SiC first wall for LiPb blanket (Sawan et al., 2011, p. 449).

Robust chamber clearing

For direct drive, target emissions for a 1 GJ yield direct drive target will include about 700 MJ neutrons, 290 MJ of ions (debris and target fuel) with the remaining 10 MJ of energy (1%) in X-rays (El-Guebaly and Malang, 2009). This level of X-ray loading to first surfaces inside the chamber, assuming 3.5 to 5 m radius, will be of order $\frac{1}{4}$ to 1.5 cal per cm^2 and little material will be liberated by these X-rays. While the D-T fusion reaction itself emits a 14.1 MeV neutron, 80% of the net energy release of the reaction, and a 3.5 MeV He atom nucleus or alpha particle with the remaining 20% of the energy, neutron scattering in the high-density region of the burning target results in a net transfer of about 10% of neutron energy to the debris and fuel ions. The target emissions are important because whether the chamber has a bare first wall, wetted first wall, or a flowing blanket inside the chamber, the target material itself and any material liberated by the intensities of X-rays and/or ions must be sufficiently cleared to allow both the next direct drive target injection into an environment where it will survive to chamber center and until the driver energy arrives in a sufficiently cleared environment to reach the target and properly irradiate it.

For indirect drive, target emissions for a 1-GJ indirect drive target will again include 700 MJ of neutrons and a much more substantial portion of the emission in X-rays, some 250 MJ, leaving only 50 MJ of debris that is emitted over tens to hundreds of microseconds. The X-ray emission is relatively short—with emission through the target beam entrance holes (for laser indirect drive) completed in about 20 ns—and X-rays emitted from the walls of the target over some 100 ns since this is simply the radiation of energy from the hot debris—and characterized as a ~ 100 eV blackbody—while the entrance hole emission will be hotter— ~ 300 eV blackbody. This level of X-ray loading to first surfaces inside the chamber, assuming 3.5–5 m radius, will be of order 20–40 cal per cm^2 and substantial material will be liberated by the X-rays on each shot—thicknesses of tens to hundreds of microns. For example, if the first wall is a wetted wall of liquid Li, then this would liberate 2 kg of vaporized Li per shot that must be removed or condensed prior to the next target being injected and the next irradiation taking place. For a spherically shaped chamber, this material would also be launched perpendicular to the surface toward chamber center perhaps increasing the difficulty of quickly clearing this material.

The direct drive emissions therefore produce fewer challenging conditions for chamber clearing than indirect drive due to its substantially less X-ray emission.

Much more research is needed to be done to resolve whether the liquid first wall options using FLiBe or FLiNaBe eutectic salts that are liquids at the chamber operating temperatures discussed in this section are viable candidates for an IFPP. This is also extremely dependent on IFPP design parameters such as repetition rate and fusion yield. While no research is fully conclusive on these points, indications are that a small repetition rate IFPP (1–2 Hz) that uses modest yields (~ 1000 MJ yield) might succeed based on predicted condensation times. The reference (Raffray et al., 2006) includes an excellent summary of all of the computational tools (4) and experimental facilities (7) around the United States that have been used to research aspects of this very complex issue.

Robust target design and affordable target fabrication

Target fabrication, executed for the past 50+ years for a few shots per day and where target cost is seldom a driver for ICF research, will be a challenging task for Inertial Fusion Energy. First, the DT fuel being loaded into capsules must be maintained at ~ 18.5 K with temperature fluctuations less than ± 0.5 K after fabrication and during transport to the target injection system. Direct and indirect drive capsules are filled by using a very small fill hole (typically 5 μm in diameter) and fill tube to pass the cryogenic DT into the capsule. Tritium beta-decay is then used to smooth the fuel into layers that meet the 1- μm RMS surface finish. The mating of the capsule to its hohlraum is a slow high precision step where quality assurance is present in each step as two hohlraum halves are mated trapping the capsule that has been emplaced in a membrane. An IFE power plant operating at 0.1–20 Hz will need to fabricate and inject into the chamber from 8640 to 1,728,000 targets per day.

The LIFE project effort at LLNL from 2010 to 2014 conducted the most extensive study of indirect drive target manufacture to support IFE power plant needs. LLNL concluded that a Pb-based indirect drive target with a total mass of 4 g could be made for \$0.30 each to support a 16-Hz repetition rate. Lead was chosen as an affordable substitute for the gold that has been used in the vast majority of the thousands of hohlraums employed in experiments at LLNL on the NIF and at other facilities such as the Omega laser (Miles et al., 2011). This target is shown in Fig. 20.

Target performance modeling and supporting experiments on Omega were conducted to indicate similar target performance for lead as for gold for a somewhat larger laser driver energy of 2.2 MJ over the 1.8 MJ. Another excursion in building LIFE targets compared to NIF would be to employ 20–30 mg/cm^3 CH foam to wick liquid DT into a stable fuel layer in lieu of the time consuming and therefore unaffordable beta-decay layering and smoothing techniques. A modified gain of about 60, which met the LIFE requirement, is therefore assumed in lieu of the clean 1-D calculation resulting in a gain of about 100. A “rugby ball” shape also replaces the traditional cylinder reducing the interior surface area by some 30% thereby reducing the total laser energy required.

The LIFE effort assumed it would be less expensive to simply throw away the 35 kg to up to 7000 kg per day of target material than to develop a means to recycle since lead was described as being only \$1 per pound or a daily throwaway cost of \$77 to \$15,400 or an annual cost of \$28 k to \$5.6 M. Further substantial scaling up of current target fabrication capabilities will be required such as chemical Carbon Vapor Deposition machines with single batch sizes of about 45,000 capsules per batch.

The 2013 US National Research Council Report on ICF Targets said:

Fig. 20 LIFE (laser inertial fusion energy) target concept (Miles et al., 2011).

The primary concern of this panel with regard to ICF target fabrication relates to the technical feasibility of various proposed fabrication methods and the remaining technical risks and uncertainties associated with these methods. The question of whether the targets can be made cost-efficiently for a power plant is beyond the purview of this panel and is addressed by the National Research Council's IFE committee. [A] promising approach [is]:

Microfluidic Methodologies for Manufacturing Targets. The polymer shell that contains the DT fuel for DD laser and heavy-ion-beam fusion is proposed to be manufactured using a microfluidic droplet formation method. This is an established technology that is used to make ICF capsules for current DD and ID experiments. The principle is to flow three immiscible fluids coaxially through two nozzles where the Rayleigh-Plateau instability that occurs in the region where they intersect produces individual droplets. Each droplet is an emulsion consisting of a thin shell of water surrounding a spherical oil droplet; these droplets are collectively immersed in oil. The thin shell of water contains the polymer precursors that form the plastic capsule. The final phase of the production process is to remove the fluids using supercritical drying.

This process has a very high production rate that is needed for a fusion energy program. However, the repeatability and precision of the process must be improved if the process is to be a viable option for an energy program. (The repeatability of the current process does not ensure that each capsule meets the required specifications, so each capsule is individually measured to determine its suitability; this raises the cost of the targets, which is acceptable for ICF experiments but not for an IFE program.) In all other aspects, this production process offers a potentially viable method for producing targets cost-effectively.

One modification to the current microfluidic method that may improve the reliability is to introduce electromechanical control into the process (Cho et al., 2003). This process, referred to as "lab-on-a-chip," has demonstrated the feasibility and benefits of using electric fields and electronics to control important steps in the target production process (Bei et al., 2010; Wang et al., 2011). This concept can potentially reduce the production time and physical size of a target production facility and address the precision and reliability concerns with the existing process. Further development of the process is needed.

The lab-on-a-chip concept is being evaluated as a method to accomplish the cryogenic operation of loading the DT fuel into the capsule. Preliminary proof-of-concept experiments show that it is possible to form individual droplets of liquid deuterium of the correct size and wick them into a foam capsule in a short period of time. This would have the benefit of simplifying the target fueling process and shorten the process time, which would reduce the tritium inventory that is required by an IFE plant. Additional work is required to further develop this concept—specifically, to demonstrate that the process works with tritium and that it is practical to apply a condensed gas (argon, neon, or xenon) seal-coat onto the capsule once the fuel is loaded (NRC, 2013a,b, pp. 85–86).

In 2013 the US National Research Council Assessment of the Prospects for Inertial Confinement Fusion Energy Systems stated:

The scientific challenges to IFE target fabrication lie primarily in understanding the physics behind the specifications for inertial fusion target requirements: sphericity, uniformity and smoothness (How good is good enough?), and understanding the physics and chemistry behind the ability to achieve those requirements (Which physical processes control sphericity, uniformity, and smoothness?) Experiments with IFE targets at the NIF can help provide the physics understanding. The engineering challenges lie in selecting and developing materials that can achieve these requirements and in developing the processes and equipment needed to do so reliably and repeatedly with very high yield at reasonable cost. The specific requirements appear at present to include these:

The ability to fabricate IFE targets that meet specifications such as those for indirect drive:

- Capsules with 4 mm diameter, $< 1 \mu\text{m}$ sphericity, $\sim 100 \mu\text{m}$ wall with $< 0.5 \mu\text{m}$ tolerance, $< 200 \text{ rms}$ surface smoothness, surface power spectrum below the NIF capsule profile.
- Hohlräume fabricated to $\leq 10 \mu\text{m}$ accuracy. Targets assembled to $\leq 10 \mu\text{m}$ accuracy.

And those for direct drive:

- Foam shell capsules with $\sim 150 \mu\text{m}$ thick with $< 0.5 \mu\text{m}$ tolerance and $\sim 4 \text{ mm}$ diameter with $< 1 \mu\text{m}$ sphericity. Foam density $\leq 100 \text{ mg/cm}^3$ with cell size $< 1 \mu\text{m}$. A seal coat on top of the capsule having a $1\text{--}5 \mu\text{m}$ wall with $< 0.5 \mu\text{m}$ tolerance, $< 200 \text{ rms}$ surface smoothness, and a surface power spectrum meeting the NIF/NIC required profile.

A projected cost of mass-producing IFE targets for a power plant of $\leq \$0.50$ each (NRC, 2013a,b, p. 99).

The objectives of IFE target fabrication R&D must be to understand the physics behind the specifications for inertial fusion target requirements and understand the physics behind the ability to achieve those requirements to such a depth that target materials can be selected and/or developed that meet target specifications, and processes and equipment can be developed to do so reliably and repeatedly with very high yield at reasonable cost. The report concluded that target fabrication at the quality and production rate needed appears possible with continued development.

Robust high rep-rate target injection and tracking

The challenges for injection of a direct drive target to chamber center for IFE are: first, provide enough velocity on each target to maintain the required shot rate; second, accelerate the target in a way that avoids damage to the fragile frozen layers in the capsule; third, allow no more heating from the chamber walls or “atmosphere” to the target than 0.5 mK ; fourth, detect the target location to within $20 \mu\text{m}$ at shot time to ensure small beam alignment adjustment gives optimal irradiation; and fifth, ensure the driver energy arrives at the target in the designed power format and pulse duration to drive the target to the design gain and yield.

If the distance to chamber center is $3\text{--}6 \text{ m}$, then to support a shot rate from 0.5 to 20 Hz , target velocities to chamber center are shown in Fig. 21.

So, in addition to chamber clearing times, the IFE power plant shot rate will be limited not only by driver repetition rate capabilities but also by successful target survival to chamber center due to both chamber wall and/or atmospheric heating and acceleration forces.

The NRC 2013 Assessment on IFE made the following comments on rapid target injection:

After the targets have been fabricated, they must be injected into the chamber. For laser drivers and accelerators, several methods of ballistic injection have been suggested, including gas guns and electromagnetic accelerators. For present pulsed-power fusion system designs, the targets are attached directly to the end of a transmission line. In this case, the targets and a replaceable transmission line are inserted into the chamber mechanically. [We] consider only ballistic injection.

Gas guns have been built at LBNL and at General Atomics. These have been used to accelerate surrogate targets to high velocity ($> 100 \text{ m/s}$). In the case of direct drive, the targets must be carried by some kind of sabot to protect the target as it is accelerated in

Fig. 21 Minimum target (direct or indirect drive) velocities needed as a function of chamber radius and shot rate.

Fig. 22 The LIFE concept would use a 9-m long injection system to launch indirect drive targets to chamber center (Miles et al., 2011).

the gun barrel and injected into the chamber. The sabot is removed either mechanically (with a spring) or magnetically. The gas gun experiments have demonstrated high-repetition-rate injection, including separation of the sabots from the targets, in a burst mode (Goodin et al., 2003). In these experiments, the placement accuracy at a distance of 20 m was about 10 mm. This 10 mm includes the contributions from the accuracy of the gun and from the separation of the target from the sabot. Estimates of the placement accuracy for indirectly driven targets (no sabots required) are much better than 10 mm. This is adequate for subsequent target tracking and beam steering, as discussed in the next section. In summary, one can unquestionably build devices to inject the targets at adequate velocities and repetition rates. The remaining challenges are associated with wear and long-term reliability and durability, particularly in a fusion environment. The report concluded that target injection techniques have been developed in the laboratory that are adequate for subsequent target tracking and steering and that appear to be scalable to meet the inertial fusion energy requirements for speed and accuracy (NRC, 2013a,b, pp. 100–101).

A target injector for the LIFE concept was also designed and is shown in Fig. 22. It uses a 9-m long injection system with a rotating shutter shield to prevent neutron heating of targets waiting to be injected. The goal of the injection system is to place the target within 500 μm of chamber center so that final optics can steer beams in the final 25 μm to engage the target (Miles et al., 2011).

The target tracking system (see Fig. 23) detects the target when it is only 6-mm away from chamber center using a tracking laser beam array that produces a glint from the target that can be detected using the same final optics as for the main beams. The accuracy of beam engagement to the target is calculated to be as good as 10 μm using this system and well within the target specification of 100 μm (Miles et al., 2011). This system may be challenging to be implemented successfully for a chamber concept that employs liquid first walls and has a high shot rate.

The 2013 NRC Assessment of IFE further stated:

Fig. 23 The schematic of the LIFE target tracking and engagement sensor system (Miles et al., 2011).

The uncertainty in position of the targets when injected is much larger than the alignment precision of the driver beams relative to the target needed for ignition. Typically, the required alignment precision is approximately 20 μm for both laser and ion direct drive (Carlson et al., 2010). For NIF-like, indirectly driven targets, the required precision is approximately 80 μm . For ion-beam indirect drive, the requirement is calculated to be 100–200 μm , depending on the size of the hohlraum. Given this situation, it is necessary to track the position of the target and to point the driver beams at the target. At least two methods of target tracking have been demonstrated. One tracks the shadow of the target using light-sensitive sensors. The other relies on the reflection (“glint”) off the target. A scaled experiment performed by the University of California at San Diego and General Atomics demonstrated a beam alignment of 28 μm (Carlson et al., 2010). An alignment precision of 28 μm is nearly good enough, even for direct drive. Improvement to 20 μm seems possible, although advanced concepts such as shock-ignition targets may require still more precise alignment. The remaining challenge is to scale the technique to full size and full target velocity and demonstrate that it works reliably in a fusion environment. In a fusion environment one will undoubtedly have to deal with rapidly changing temperatures, mechanical vibration, and degradation of components by radiation.

The pointing of laser beams is usually done mechanically using a rapidly moving optical element. For accelerators, the beams can be pointed by pulsing relatively weak dipole magnets. For the beam parameters usually associated with ion indirect drive, this technique does not appear to be challenging. On the other hand, it may be necessary to put a significant energy spread on the ion beams to achieve the beam pulse durations needed for shock ignition or fast ignition. Energy spread produces dispersive effects in magnetic fields, so more work is needed to establish pointing feasibility for these options. [The report concludes that] target tracking and laser-beam-pointing methods that are adequate for indirect drive have been developed in the laboratory; direct drive will require higher precision (NRC, 2013a,b, p. 101).

Affordable activated material management

The challenges with target material management mainly apply to indirect drive targets. For an indirect drive target, in a 50-year plant lifetime at 90% availability, operating at 20 Hz and using the lead 4-g LIFE target, some 300 tons of low-level radioactive material would be produced if the lead was a once-through material expense. Studies (Latkowski et al., 2000) also suggest that while fusion will largely avoid material that can be rated high level waste, it will overwhelm low level waste repositories with extremely large volumes of material—even not including the activated target material.

The 2013 NRC Assessment of IFE states:

All targets produce radioactive materials—unburned DT fuel if nothing else—that must be recycled. Nevertheless, targets for laser direct drive produce orders of magnitude less high-Z material than indirectly driven targets for both lasers and ion beams. Although the indirectly driven targets have the advantage in terms of injection, direct drive has the advantage in terms of recycling. Most direct-drive (actually mixed-drive) ion targets also contain significant quantities of higher-Z material. In the case of pulsed-power fusion, the target materials themselves are dwarfed by the transmission line structure that is destroyed on each pulse.

There is currently little agreement on how to handle the high-Z materials such as Pb, Au, and Pd. These materials will be activated to some extent and will have to be considered as radioactive waste. Some researchers believe that it is preferable to use new material, such as lead, for each target (El-Guebaly et al., 2006). In this case, there is a significant waste stream, but it is only mildly radioactive. In contrast, the LIFE team proposes to recycle the lead used for the hohlraums (Dunne et al., 2011a,b; Latkowski et al., 2011). All surfaces in the reactor and vacuum chamber are designed to operate at temperatures exceeding the melting point of lead. The molten lead is collected and recycled. For liquid-wall chambers using lithium or molten salt, the hohlraum materials would have to be removed from the liquid. There are a number of trade-offs involved in the choice of hohlraum material. Some materials are better than others in terms of target performance. Some are better in terms of activation, toxicity, and cost. Finally, some are easier to separate from the chamber liquid.

For IFE concepts with wetted or liquid wall chambers, it may be possible to make the targets from materials that are constituents of the chamber coolant. Lead hohlraums for use with LiPb coolants and frozen-salt hohlraums with a high-Z liner for use with liquid-salt coolants may be possible.

There has been significant research on nearly all of the issues associated with handling and recycling the target materials (El-Guebaly et al., 2006). Determining the optimal methods and materials and demonstrating commercial feasibility remains an important challenge. [The report concludes that] target materials recycling issues depend strongly on the inertial fusion energy concept, the target design, and the chamber technology. Direct-drive targets have fewer concerns in the area of recycling and waste management; indirect-drive target materials handling, recycling, and waste management will need further development (NRC, 2013a,b, pp. 103–104).

Of particular importance are those waste streams that are considered “mixed waste.” Mixed waste has both a chemical hazard and a radiation hazard; irradiated lead is an example of a mixed waste. Lead is a coolant candidate as well as a target material candidate. Mixed waste currently has no disposition path in the United States, but regulations governing its disposal are under development and would likely be in place before deployment of the first commercial fusion plant.

[There report concludes that] design studies of inertial fusion energy power plants indicate that, with the use of low-activation materials, it will be possible to minimize high-level waste. However, the amount of waste that requires disposal, albeit near the surface, may be very large. Low-level waste disposal in the United States is becoming increasingly difficult [and further recommends continuing] studies that examine the potential for recycling and reuse of radioactive materials within the fusion system to reduce the amount of material that must be disposed of (NRC, 2013a,b, p. 134).

Target materials for inertial fusion energy (IFE) power plant designs might be selected for a wide variety of reasons including wall absorption of driver energy, material opacity, cost, and ease of fabrication. While each of these issues are of great importance, target materials should also be selected based upon their safety and environmental (S&E) characteristics. Previous studies have traditionally focused on the recycling, waste management, and accident dose characteristics of potential target materials (Latkowski et al., 2000; El-Guebaly et al., 2004).

It is clear that indirect drive targets, typically designed within a high-Z material hohlraum or enclosure around the D-T pellet, contain materials that need to be disposed or recycled after each target use. Previous studies on indirect drive targets have proposed the use of Au, Gd, W, Pb, Hg, Ta and combinations of these (El-Guebaly et al., 2004). The choice of target materials has a definite impact upon the fuel cycle design and the power plant material disposal/recycling strategy.

Analyses published to date (El-Guebaly et al., 2004) show that target materials represent a small stream compared to that for the nuclear island. However, recycling continuously during plant operation will contribute to public acceptance and may improve the economics of the plant life-cycle through more favorable waste categorization.

Efficient tritium production, recovery, and management

From the NRC Report on IFE:

Tritium production, recovery, and management are key to the success of an IFE system. The supply of tritium on Earth is limited (half-life ~ 12.3 years), so tritium “breeding” is required to ensure a ready supply of fuel for IFE. Tritium self-sufficiency (the “closed” fuel cycle for fusion) is necessary for commercial success or even large-scale test facilities. This requirement brings with it a range of issues, including target performance, tritium breeding potential of the blanket, and the tritium inventory in the IFE system. Because tritium is hazardous and readily mobile under certain conditions, there is a trade-off between tritium inventory and safety.

Several design studies have evaluated tritium-breeding performance and associated tritium inventories (DOE, 1992; Dunne, 2011a,b). These studies provide a useful first examination of these issues. The quantitative conclusions from all such studies must be viewed as somewhat uncertain, because they are at a relatively high level and miss many of the issues that become apparent when a system is actually built at engineering scale, revealing, for example, the actual area available for tritium breeding once all the equipment, manifolding, and such are considered.

The tritium inventory in the target fabrication plant is highly dependent on the target performance (lower performance means higher tritium inventory in the targets) and on the process used for target fabrication. Depending on the target fabrication process, tritium inventories in the target fabrication plant can be as large as 10 kg. Important in the consideration of tritium inventories is the ability to recover the unused tritium from the unburned DT fuel as higher burn fraction results in less tritium to recover. In the LIFE concept, estimates suggest that about half of the tritium inventory will be in the target fabrication plant, and total tritium inventory in the LIFE system is < 600 g (Dunne, 2011a,b). The SOMBRERO design study claims a similar (300 g) tritium inventory in the target fabrication plant (DOE, 1992).

Tritium breeding is accomplished in the blanket. IFE and MFE share tritium breeding needs and basic blanket concepts. The section on reaction chambers above summarizes the types of chambers under consideration for IFE; they fall into two main categories: solid walls and liquid walls. Liquid lithium is an option for liquid walls and has the advantage of relatively high tritium solubility, thus reducing tritium permeation concerns; however, that high solubility can result in undesirably high tritium inventories. Tritium recovery systems have been partially developed and tested at laboratory scale and indicate that acceptable tritium removal and thus inventory limits can be met with these processes; further testing at laboratory and engineering scales is needed to confirm this. Liquid lithium is a superior tritium-breeding medium (compared with molten salt and LiPb) and is therefore attractive from a tritium self-sufficiency point of view. Molten salt (e.g., FLiBe) and LiPb have the advantage from a safety point of view (El-Guebaly and Malang, 2009) of reduced tritium inventories and less chemical activity; however, they have low tritium solubility and thus a higher driving force for permeation (a safety disadvantage) and may require tritium permeation barriers to control the movement of tritium throughout the system. The SOMBRERO design is considerably different from most other IFE designs: it utilizes a granular Li_2O blanket (using gravity to move the particles through the system) that serves as both the coolant and the tritium breeder (DOE, 1992). Low-pressure helium removes the tritium from the Li_2O and transports the granules to and from the intermediate heat exchangers. The tritium inventory in the SOMBRERO design was originally estimated at just under 200 g; however, later analysis indicated that the inventory may be 1–2 kg of tritium in the carbon structure, emphasizing the potential for uptake of tritium in structural materials. A large tritium inventory requires an engineering or materials solution to ensure safety under off-normal conditions. Tritium removal from ceramic breeder blankets is also a topic of interest to the ITER test blanket module (TBM) program (Albrecht and Hutte, 2000) and the IFE program can leverage those activities.

Each of these studies shows tritium self-sufficiency. However, in actual application, losses due to uptake in structure, process losses, and actual neutron economy will likely be greater than accounted for in the studies. While there are a number of ways to adjust the tritium-breeding ratio (blanket thickness, ${}^6\text{Li}/{}^7\text{Li}$ ratio, neutron multiplier), until tritium breeding studies are done for detailed designs, including testing at engineering scale, the tritium self-sufficiency of any design must be considered uncertain. Tritium management will benefit from NIF and OMEGA studies to a limited extent (particularly target fabrication, tritium management, tritium handling, and tritium processing). However, the lack of a breeding blanket in NIF leaves an important area in a state of uncertainty. There has been limited work on liquid and solid breeder blankets in the IFE context. The work in the MFE program could be leveraged. Much could be gained from taking advantage of the larger MFE blanket programs under way in other countries. Further, a workshop was held in 1992 to brainstorm uses of the NIF to advance Inertial Fusion Energy to ensure its design did not preclude any of the ideas generated. This body of ideas, which included experiments with tritium, should be reviewed today, updated, and implemented (Tobin et al., 1994).

The report concluded that tritium-breeding performance has been considered in several design studies. These provide a useful initial examination of these issues. As these studies are at a preconceptual design level, they miss many of the issues that become apparent when a system is actually built at engineering scale, tritium recovery systems have been partially developed and tested at laboratory scale, and the signs are that acceptable tritium removal—and thus inventory limits—can be met with these processes. Further testing at laboratory and engineering scale is needed to confirm this, and tritium management will benefit from National Ignition Facility (NIF) activities, particularly target fabrication, tritium management, tritium handling, and tritium processing. However, the lack of a breeding blanket in NIF leaves an important area uninvestigated (NRC, 2013a,b, pp. 125–128).

Technology for IFPP driver—Chamber—Target integration

The separability of the IFE Power Plant components is considered one of its advantages compared to MFE. However, an interface must still be made, and a key technology is the ability to allow driver beams into the chamber area without chamber emissions contaminating or damaging the IFE Power Plant driver. The neutrons, as previously discussed, are traveling too fast for a mechanical shutter to be successful, as are the X-rays. Chamber gases and target debris must also be prevented from traveling up the beamlines as well. The transport systems such as focusing optics for lasers and magnets for heavy ion beams must be protected.

A major challenge for each driver technology proposed for IFE power plants—solid state laser, excimer laser, heavy ion beams, and pulsed power—is connecting to the target chamber in such a way as to pass the driver energy into the chamber environment and successfully irradiate the target to achieve the design yield without the chamber environment (e.g., neutrons, X-rays, debris, ablated material, tritium, etc.) being realized within the driver area. This section describes the technologies that allow this to happen.

Indirect and direct drive IFPP using solid state lasers

Table 2 gives a set of laser parameters for a diode-pumped solid-state laser for the Laser Inertial Fusion Energy (LIFE) IFPP using indirect drive targets.

A continuous phase plate (CPP) is used to produce a focal spot of 3.1 mm enclosing 95% of each beam's energy. The CPP also modifies the far field beam from a peak to a flat top for target drive purposes. A spectral bandwidth at 0.351 nm of 180 GHz suppresses Stimulated Raman Scattering (SRS), Stimulated Brillouin Scattering (SBS) and with a diffraction grating for Smoothing by Spectral Dispersion (SSD) of the laser speckle created by the CPP onto the target. There are 384 separate beams divided into 48 groups of 8 beamlines (Bayramian et al., 2011).

Table 2 Laser system requirements for diode-pumped solid-state laser IFE for indirect drive (Bayramian et al., 2011).

<i>Characteristic</i>	<i>Requirement</i>
Total laser energy at 351 nm (MJ)	2.2
Total peak power (TW)	633
No. of beam lines (48 groups of 8)	384
Energy per beam line at 351 nm (kJ)	5.4
Wall plug efficiency at 351 nm (%)	15
Repetition rate (Hz)	16
Lifetime of system (shots)	3×10^{10}
Availability (99%)	99
Beam pointing (μm RMS)	100
Beam group energy stability (8 beams) % RMS	< 4
Beam-to-beam timing at target (ps RMS)	< 30
Focal spot (mm)	3.1
Spectral bandwidth, 3ω (GHz)	180
Prepulse at 20 ns prior to main pulse (W/cm^2)	< 10^8

Fig. 24 Fused silica wedges can be used to deflect the beam out of the line of sight of the target (IAEA).

For laser drivers, approximately 3% solid angle of the chamber is open due to beamlines. The most plausible option to protect the final optics from chamber emissions for either direct or indirect drive is to use two optical wedges in line to shift the most sensitive optics out of the line of sight of the target chamber center as shown in [Fig. 24](#).

Fused silica will form color centers due to the neutron irradiation levels for IFE Power Plants at distances of about 40 m from chamber center and fusion power levels of 2000 MW_{fusion} which results in $\sim 3.5 \times 10^{12}$ neutrons cm²/s. However, it is possible to anneal the color centers even as they are made to keep the transmission reduction to well less than a few tenths of a percent if the optic can be kept at temperatures of about 350 °C. X-rays from indirect targets must also be mitigated from reaching the fused silica at fluences above 1 J/cm. This can be easily done by puffing a noble gas such as xenon into the beam line on a continuing basis maintaining ~ 1 mg/cm² gas density. This is a sufficiently small amount injected well up beam lines that vacuum pumps will remove this gas before it reaches chamber center and can affect aspects like keeping the target cold and/or injecting the target correctly. Direct drive targets do not need to protect final optics from X-rays but must protect them from debris ions emitted from the target. The same level of gas protection for X-rays will also stop debris ions from reaching the fused silica ([IAEA, 1995](#)).

Grazing incidence mirrors are also an option for 0.351 wavelength laser light to bend the light out of the direct line of sight of the target emissions exiting the chamber beam port. Grazing incidence mirrors work by accepting light at a very shallow angle (typically 6 degrees) where for a sufficiently polished and flat surface the light will be reflected at the same angle such that the beam is 12 degrees off axis from the chamber center. In [Fig. 25](#), the final optics elements design for the Prometheus IFE Power Plant concept, the grazing incidence mirror employment can be seen in conjunction with turning mirrors. A dielectric optic focuses the beam onto the first turning mirror setting the laser pulse spot size.

Fig. 25 Final optical [GIMM] elements in the Prometheus IFE Power Plant design ([Moir, 1999](#)).

Direct drive IFPP using excimer lasers

The KrF driver system consists of (1) a front-end which produces a pulse with the desired band width and temporal and spatial intensity characteristics; (2) several stages of intermediate amplification and progressive temporal/angular multiplexing; (3) final amplification by large electron-beam pumped 2-pass amplifiers; and (4) demultiplexing and beam delivery to the IFE power plant chamber (DOE, 1992).

Since electron beam amplification typically is most efficient in pulses of 500–1000 ns, significant temporal compression of each beam is required before it can be sent to the target. This is accomplished through a multiplexing system that uses arrays of mirrors to slice the long pulse beam into 100 smaller beams each 1/100th of the pulse duration of the long pulse to recombine the beams into the shorter pulse length. In Table 3, for example, the 600 ns pulse is shortened to 6 ns but generating 100 beamlets per beamline and then recombining them into 60 pulses at a pulse length shorter by a factor of 100.

Due to the very short wavelength of KrF and ArF, the use of fused silica wedges to direct beams out of the line of sight of chamber emissions is not feasible due to the much lower laser damage threshold and the added B integral. Multi-layer dielectric mirrors experience high damage rates due to neutrons and are therefore a poor candidate. The only credible means to adjust the directionality of the short wavelength beams (< 300 nm) such that streaming neutrons, debris, and X-rays from the chamber can be avoided is by the use of a Grazing Incidence Mirror (GIM) for each beam line. Two types have been studied: Grazing Incidence Metal Mirrors (GIMM) and Grazing Incidence Liquid Metal Mirrors (GILMM).

The leading choice for a GIMM are solid solution aluminum alloy mirrors due to the very high reflectivity of Al deep into the UV part of the spectrum (Tillack et al., 2009). Operation at a grazing angle such as 85 degrees with properly polarized light substantially increases reflectivity and increases the beam footprint by $10 \times$ thereby reducing the incidence fluence as shown in Fig. 26. It appears that defects (such as surface contamination) can be tolerated up to 1% of the laser wavelength suggesting that for ArF such contaminants would need to be limited to 2 nm in size (Tillack et al., 2002).

An option in lieu of a GIMM was proposed, the GILMM.

[For grazing incident liquid metal mirrors (GILMM),] a thin film of liquid metal serves as the robust final optics. The amount of laser light the GILMM can withstand is 57 J/cm² normal to the beam for a 20 ns pulse of 0.35 μ m light set by restricting the surface temperature rise to 200 degrees C to limit liquid ablation. Liquid aluminum can handle 106 J/cm². The liquid surface is kept to the required flatness by a combination of polished substrate, adaptive optics, surface tension and a low Reynolds number laminar flow in the film. The film's substrate must be polished to 15 nm. Surface tension keeps the surface smooth over short distances (~10 mm) and low Reynolds number laminar flow keeps the surface smooth by keeping the film thickness constant to less than 10 nm over distances > 10 mm. Adaptive (deformable) optics techniques keep the substrate flat to within 60 nm over 100 mm distances and 600 nm over 1 m distances. The mirror can withstand the X-ray pulse when located 30 m away from 400 MJ micro-explosions (50 MJ X-rays) when Li is used but for higher atomic number liquids like Na and Al there may be too high a temperature rise forcing use of other X-ray attenuation methods such as xenon gas, which may be needed for first wall protection anyway. The cumulative damage from neutrons causing warpage of the liquid film's substrate can be compensated by adaptive optics techniques giving the mirrors long life, perhaps 30 years. The GILMM should apply to both direct and indirect drive laser pulse lengths (Moir, 1999, p. 1).

Table 3 KrF laser parameters for the direct drive sombrero life power plant concept (DOE, 1992, p. 25).

Characteristic	Requirement
<i>Laser</i>	
Total laser energy at 248 nm (MJ)	3.6
Number of beam clusters	60
Beamlets per cluster	100
Final pulse duration (ns)	6
Repetition rate (Hz)	6.7
Total peak power (TW)	600
Wall plug efficiency (%)	7.5
Spectral bandwidth, 3ω	3 THz
<i>Electron-beam amplifier</i>	
Amplifier Energy (kJ)	60
Ar in Kr (%)	50
Pressure (Atm)	1
Initial temperature (°C)	500
Pumping (kW/m ³)	400
Extraction time (ns)	600
Amplifier gain	16
Lengths in optical, flow, and E-beam directions (m)	1/2/1
Fluence (J/m ²)	5
Electron-beam voltage (kV)	610
Diode current (A/cm ²)	40.6
Inductance (nH)	23
Applied field (kG)	6
Intrinsic efficiency (%)	14.5

Fig. 26 A section of the elevation view of the Sombbrero IFE Power Plant showing the orientation of the grazing incidence mirror and the final turning mirror (DOE, 1992, p. 226).

Fig. 27 Grazing incidence liquid metal mirror (GILMM) concept (Moir, 1999, p. 6).

A grazing incidence liquid metal mirror typical layout is shown in Fig. 27.

Direct and indirect drive IFE using heavy ions

The Robust Point Design-2002 (RDP-2002) Heavy Ion IFE Power Plant concept, the most recent HI IFE Power Plant study, adapts the most recent heavy ion target design to an updated power plant concept by now including 120 penetrations into the chamber (Yu et al., 2003). First wall protection and shielding for key components of the accelerator beam line is still achieved by using eutectic salt jets as in the HYLIFE-II IFE Power Plant concept but now a substantially larger number of jets are required as shown in Fig. 27.

The heavy ion beam chamber interface is complicated. First the final beam transport employs a bending magnet to direct only the last 10–20 m of beamline into line of sight with the chamber ports. This minimizes the region that must be protected by neutron shielding but of course includes the superconducting focusing magnetics. Just past the last focusing magnet in the RBD-2002 heavy ion beam driver they designed a 50-cm section that had 20-cm dipole at 1 kG and a 20 cm pulsed plasma source with an average of 10^{14} ions per cc. These performed the dual function of plasma “plug” for beam neutralization and as a magnetic shutter to remove target debris. The plasma shutter was timed to be on as the beam passed into the chamber assisting beam neutralization in the 6-m transport to the target. This also prevents plasma from passing into the beam transport section where good vacuum is needed. A second plasma “plug” is at the end of the tube enhancing neutralization after transit. In the reverse, the same components act as a magnetic shutter preventing target debris from passing up the beam tube. Vortices of the liquid eutectic salt are also set up that coat the beam tubes that penetrate the solid shielding and chamber walls. Scaled experiments using water have demonstrated that each of these three jet types can be created (Fig. 28) (Yu et al., 2003; Abbott et al., 2001; Pemberton et al., 2001).

IFE using pulsed power

Pulsed-power-driven IFE would use ≥ 50 MA of current from a pulsed power accelerator to create very large magnetic field fields that would in turn compress and heat magnetized D-T fuel to produce fusion yield. This approach has relatively low-cost, high-efficiency

Fig. 28 A complex arrangement of crossing jets and oscillating jets protect the first wall (Yu et al., 2003, p. 4).

Fig. 29 The magnetize liner inertial fusion (MagLIF) concept using a liquid wall chamber. The target is called a recyclable transmission line (RTL) and is approximately 2-m long and 1-m wide (NRC, 2013a,b; Cuneo et al., 2011).

driver technology that may be directly scalable to the peak powers and energy needed for IFE. It appears feasible to perform these functions at a repetition rate of perhaps 0.1 Hz. This approach is called Magnetized Liner Inertial Fusion (MagLIF) as shown in Fig. 29 (NRC, 2013a,b).

While the approach appears relatively simple with a cylindrical target geometry and highly efficient delivery of driver energy to fuel implosion and heating, there is considerable uncertainty and technical risk surrounding all aspects of this approach limited relevant experimental data on target physics and ignition and a lack of in-depth design studies on inertial fusion reactors at the proposed multi-GJ yield and ~ 0.1 Hz repetition rate.

In addition to MagLIF, there other promising approaches to pulsed power fusion energy, including one called magnetized target fusion (MTF). While MagLIF operates on the 100-ns timescale, is ~ 1 cm in size, and involves open magnetic field lines, MTF operates on a ~ 1 μ s timescale, is tens of centimeters in size, and involves closed (field-reversed) magnetic field lines (NRC, 2013a,b, p. 78).

Unlike any other concept for IFPP, the pulse power option does not require any special mechanism to protect the driver from chamber emissions since it is a closed system and brings its energy to initiate the fusion reaction through conducting media rather than by transport through air. The only consideration would be appropriate load-matching to the Replaceable Transmission Line (RTL) to drive the 50 + MA of current through to the fusion fuel. Since the RTL weighs some 50 kg, the main issue with this concept is rapid enough replacement and disposal of this mass and fabricating them at the rate of one every 10 s.

Summary of IFE chamber technologies

Table 4 summarizes the information in section *Supporting Technologies for IFPP* in a way that shows the logical possible technology options for the combined driver-target-chamber interfaces.

Table 4 Technology options for IFE power plants (NRC, 2013a,b, p. 114).

	<i>Solid wall</i>		
	<i>Thick liquid wall</i>	<i>Protective gas</i>	<i>Vacuum</i>
Primary advantage	Heavy ions (HI); Pulsed power (Z) Fewer materials issues with X-rays, ions, or neutrons. Thick liquid also breeder/coolant.	Laser indirect drive Fewer first wall X-ray or ion material issues.	Laser direct drive Simplicity
Primary challenge	Chamber clearing/beam propagation, target placement	Chamber clearing, laser propagation in non-uniform gas density	First wall resistance to helium retention, surface morphology change, and mass loss.
Target survival	Hohlraum thermal insulation	Hohlraum thermal insulation	IR protective layer, start target cold
Driver target coupling	(HI) Accurate target injection. (Z) Target part of RTL: automatically aligned	Inject target close enough to chamber center to allow laser mirrors to be steered to required accuracy.	Inject target within 1 cm of chamber center, detect glint from target, and steer laser mirror to required accuracy.
Resistance to emissions of X-rays, ions, and neutrons	Thick liquid resistant to all emissions, including neutrons	6 $\mu\text{g}/\text{cm}^3$ xenon gas (760 mTorr at STP). Modeling: gas stops X-rays, reemits later peak wall $T < 850^\circ\text{C}$	Engineered tungsten or magnetic intervention
Chamber recovery: Rep-rate and clearing	(HI) Oscillating liquid jets sweep chamber (Z) Metal “waterfalls” protect walls; RTL obviates clearing	Recycle 0.5% of gas between shots.	Evacuate the chamber; well within commercial technology
Breeder; coolant	Thick liquid	Lithium, behind first wall	FLiBe or PbLi behind first wall
Chamber repetition rate and clearing issues	(HI) Do oscillating jets sweep out enough ionized/atomized liquid for driver propagation and target injection? (Z) Demonstrate RTL concept with scaled experiments.	Target survival and adequate quality laser propagation through residual hot Xe or Xe/Pb gas/plasma	Only gas load is from vaporized direct-drive target ~ 0.025 mTorr per shot
Chamber chemistry issues	Proposed liquid: FLiBe also maybe Na. All are very reactive. Must stay “chemically locked up” when subject to X-rays, ions, and heat	Effect of lead liquid / vapor (from hohlraum) on wall and optics. Deposition of carbon-tritium on “colder” surfaces	Should be no chemistry issues with tungsten wall. Deposition of carbon-tritium on colder surfaces
Other critical issues	(Z) RTL “insertion hole” needs protection from emissions	Target survival/laser focusing experiments	He retention; finish target warm-up

Supporting Technologies for IFPP

Fusion neutronics and modern tools and methods

Basics of fusion neutronics and radiation transport simulations

In IFPP using tritium-deuterium fuel, 14.1 MeV neutrons are produced in the burning target. Depending on the fuel density where they are born, the neutron *energy* spectrum emitted could differ from that of the *neutrons* produced in lower or higher densities. This must be taken into account for accurate neutronics calculations in IFPP and accurate calculations from target physics models are used.

Once the neutrons escape the target, they pass into the chamber components. Nearly all will interact with the materials encountered. As result of the neutron transport and interactions with matter different effects are produced, all of which must be carefully tracked in order to accurately predict all of their relevant effects.

Neutrons carry the energy that during propagation in matter is transferred to an absorbing medium according to various interactions. This deposited energy is the nuclear heat source that will be used to generate electricity. As neutrons move within the system, they induce reactions to produce tritium inside the chamber in a process called breeding. Fusion power plants must be self-sufficient in T fuel production as well as produce start up fuel for IFPPs coming on-line.

Neutrons irradiation can damage materials by causing atomic displacements within the materials and inducing changes in their chemical composition in a process called transmutation. This is responsible for the accumulation of H and He gases and solid impurities in materials. Displacements and transmutation products make changes in physical dimensions and degrade physical and mechanical properties of the materials. Selecting materials that will withstand the fusion neutron environment is one of the greatest challenges in the history of materials science. Neutron irradiation can lead to health-damaging effects to people. Neutron shielding must be designed using neutronics to protect people and equipment. Shielding design is challenging since neutrons penetrate deep into materials and also interact and produce gamma rays which also must be shielded.

In neutron activation nuclei in materials are transmuted through nuclear reactions into radioactive nuclei through various reactions, for example, in an (n, γ) reaction, the material increases in mass number by one but stays as the same element. In an (n, p) reaction, the mass number stays the same but the atomic number of the material is increased by one making it a different element. Safety, maintenance and waste related analyses require: the radioactivity inventories by nuclide accumulated during operation of an IFPP, the related decay heat generated, and the resulting radiation doses from decay radiation as function of time and location in the IFPP.

The fusion neutronics goals are to establish a firm understanding by modeling the neutrons and therefore support the IFPP design with complex analyses, suggestions of design configurations and materials to be used. Computer codes and databases enable these complex analyses to be performed.

There are two main parts of fusion neutronics: radiation transport and time-dependent evolution of the radioisotope inventory. Advances in radiation transport and transmutation/activation calculations have been significant in recent years and are described here.

The Monte Carlo method is preferred in fusion neutronics to simulate neutron and gamma transport. It enables integral quantities to be estimated in a detailed space, energy, angle and time mesh, through statistical sampling of individual neutron histories from birth in the fusion reaction to death by absorption or leakage and registering any single event through the neutron life. Simulating a sufficient number of neutron histories is what makes it possible to quantify the macroscopic physical quantities of interest.

In simulating a single source particle's movement, we compute the score for a quantity of interest and call this a "tally," such as neutron energy deposited in a particular region. The average of the scores corresponding to an infinite number of histories would be the true value (true mean) of the physical quantity represented by the tally quantity scored in the simulation, again such as energy deposition. A real MC simulation that employs a finite number of histories, N , computes this average (mean value) as an estimate of the physical quantity, and also estimates the error, that is, calculates how far the estimated mean is likely to be from the true mean for a sample of length N . This difference is the variance, which is necessary to be small in most cases to have a good estimate of the value or tally.

The Monte-Carlo method is applied to solving the neutron transport problem using a continuous representation of independent variables (i.e., of the phase space domain). It enables that any physical system can be modeled in full 3D geometry without the need for approximations, and that continuous energy nuclear interaction cross-sections are used. This means that with a high-quality nuclear data base, the accuracy of the MC calculation is only affected by the statistical uncertainty of the calculation itself. However, to obtain results of sufficient precision via Monte Carlo, this is proportional to the number of followed particles, and can therefore be extremely computationally expensive. Methods must be introduced to optimize MC neutron transport simulations in order to get precise results.

Major advantages in the application of Monte Carlo transport codes for fusion neutronics over the last decade are due to the development of: (i) global and very efficient Variance Reduction Techniques; (ii) parallel computing; and (iii) use of available CAD geometry data in the Monte Carlo calculations.

Calculations that a decade ago would have been heroic or impractical, such as those involving large and complex geometry configurations with important deep-penetration and streaming effects are today tractable efficiently and reliably. One of the more difficult problems is that of coupling neutron transport and activation simulations to provide radionuclides inventories, decay heat and shutdown doses in those complex systems. Such calculations are done routinely today.

Acceleration of MC transport calculations

There are two general approaches for the MC simulation of the physical transport process. In the first, the analogue MC simulation uses probability densities corresponding exactly to the physical transport process; in the second the non-analogue MC approach uses well-founded modified probabilities or sampling distributions in such a way that can lead to the same result in the estimates of the quantities than those using the natural probabilities. The approach that converges faster to the correct results will be the preferred one, i.e., the one getting the smaller variance for the same computational time. Analogue MC transport simulations have a very limited range of application. Non-analogue MC can reduce the amount of computer time required to obtain results of sufficient precision. That reduction in time gets larger the more efficiently modified probability distributions are selected and used to obtain estimates of the quantities on interest (i.e., select a good Variance Reduction, VR, model). Parallel computing is also a means to speedup MC calculations, as the MC method is inherently parallel (particles are simulated independently). The combination of these two acceleration approaches have dramatically increased the performance of modern MC codes.

Traditionally, VR techniques were used to reduce the variance in the estimate of physical quantities confined to a localized energy, angle and spatial (phase-space) region, and a considerable expertise was needed to use them. Automated VR methods were later implemented to make their use easier. However, when trying to calculate/tally a quantity in multiple localized regions, or even to compute distributions of a quantity, such as flux or dose rate distributions, users had to accept different levels of uncertainty among the estimated quantity in the different locations or run separate calculations optimized for each individual location. For these analyses deterministic methods were preferred. The Modern VR techniques developed over the last 10 years called global variance reduction (GVR) enable determining a quantity (e.g., flux, dose rate, etc.) with uniformly low statistical uncertainty throughout the entire problem space, and not only confined to a localized region.

The most successful GVR methods rely on using information previously obtained, as fast and effortlessly as possible, on the distribution of the neutron fluxes. Two types of strategies have been implemented to obtain this a priori information: stochastic ([Davis and Turner, 2011](#)) and deterministic - giving raise to the denominated hybrid Monte Carlo/Deterministic methods ([Wagner](#)

et al., 2014). Currently, ADVANTG is the most advanced tool implementing deterministic strategies to generate VR parameters to be used by MCNP (Mosher et al., 2015). Furthermore, solutions for an efficient combination of parallel computing and the application of strong GVR techniques have been developed, avoiding a significant reduction in the efficiency of parallel computation (Turner and Davis, 2013). Optimization of GVR techniques is an active field of research.

Modern geometry modeling in Monte Carlo transport calculations

The MC method has the potential to be applied to any arbitrary 3D geometric configuration. Traditional transport simulation codes have limited geometry modeling capabilities and hence only an approximation of the realistic geometry configuration could be made available.

The efforts to overcome this problem were aimed at making use of available CAD geometry data in Monte Carlo calculations. Three types of approaches have been developed. In what is named indirect or translational approach, the use of CAD geometry data is achieved by converting the CAD data into the geometry representation used by MC codes (Wu et al., 2009; Lu et al., 2014). In the direct approach, direct tracking of MC particles on the CAD geometry is employed (Wilson et al., 2010). More recently, the unstructured Mesh (UM) geometry description approach is available in MCNP6 (Martz, 2014).

The current status is that the mentioned approaches have reached the maturity level to allow their application to real and complex design analyses not possible just a few years ago. Further advances will take full advantage of using modern computational geometry generation tools in applying MC methods to physics problems with complicated geometries.

Coupling radiation transport-activation schemes and shutdown dose rate calculations

The advances in geometry modeling and acceleration of MC transport calculations have very important implications in many types of analysis. One of the most complex is that of the shutdown dose rate (SDR) mapping, a very important issue in the nuclear design on any fusion device. Two approaches have been proposed to address the problem.

The Rigorous Two-Step (R2S) approach is of general application to most of problems and involves three steps: a neutron transport calculation to determine space- and energy-neutron flux distributions, an activation calculation to compute the decay gamma source, and finally a photon transport calculation for determining the photon flux distribution in space and energy and the resulting SDR mapping. The “two-step” denomination specifies that neutron and photon transport steps are done separately. Transport by MC enable the geometry to be represented continuously, but as for the R2S activation a discrete mesh geometry representation is required, which can limit the accuracy.

The implementation of this approach has followed different improved methods. Let’s just mention the following for reader reference. Pioneering code systems were based on the cell-based method (Chen and Fischer, 2002) and they were followed by those under the “super-imposed mesh-based” method (Davis and Pampin, 2010). The limitations due to the spatial gradients of the neutron flux and the decay gamma emission from radionuclides produced have been overcome more recently with the “cell-under-voxel” method (Sauvan et al., 2016), which does not require use of a conformal mesh. Finally, R2S systems have been developed based on the use of a conformal mesh to tally neutron fluxes and carry out activation (Eade et al., 2015; Biondo et al., 2016).

The other approach, called Direct One-Step (D1S) (Mariano et al., 2020; Sauvan et al., 2020), performs both the neutron and decay-photon transport simultaneously in the same Monte Carlo simulation. This approach is the most accurate because no discretization is needed for any variable in problems where all the radioisotopes of interest are generated from the initially present stable nuclides by pathways including only one neutron reaction; in addition, the composition change in those stable nuclides should be negligible, and the disappearance of the radioisotopes is only due to radioactive disintegrations. These conditions are fulfilled in many practical situations.

Advances on both D1S and R2S methodologies are still going on. Efforts are being devoted to increase the efficiency of MC calculations by more suited VR techniques to sample more particles in the phase-space regions that contribute to the tally SDR, not just to the determination of the neutron flux distributions (Ibrahim et al., 2015). As for R2S new capabilities, the problem of how uncertainties in the MC neutron transport calculation impact the SDR uncertainty is another subject of current interest (Ibrahim et al., 2015; Alguacil et al., 2019).

All of the fusion neutronics developments mentioned here are having and will have an impact on the nuclear analysis and design activity of future inertial fusion (as well as magnetic fusion) facilities, providing time-integrated neutronics calculations with an accuracy never thought possible before.

As fusion neutrons are produced in an extremely short time in IFE, time dependent neutron transport calculations can be also necessary to evaluate time-dependent responses, such as material damage.

The calculation workflow for advanced CAD-based Monte Carlo transport and activation simulations for IFPP neutronics is given in Fig. 30. Examples are from ITER as recognition for its driving the impressive advances in computational fusion neutronics.

Technology for IFE safety and environment

This section explains how through careful design choices, the inherent safety features of IFPPs can be optimized. By including safety and environmental considerations early in the design phase, the following objectives can be achieved: minimization of accident source terms, and therefore of radiation releases related to credible accidents, qualification for shallow land burial (which reduces the lifecycle cost), and control of tritium inventories by efficient tritium extraction from the blanket and by keeping the breeding ratio close to one.

Neutronics workflow

Fig. 30 Work-flow for modern neutronics calculations. A CAD model is converted to a radiation transport model. Variance reduction techniques such as Global Variance Reduction (GVR) substantially improve the efficiency and reduce the run times required for 3-D calculations. Coupled neutron-photon transport calculations provides nuclear responses such as tritium production, nuclear heating, H or He production in structures, displacements per atom in materials and radiation loads and dose fields. Coupling schemes for radiation transport and activation calculations provide the radionuclide inventory, decay gamma ray source and the resulting decay heat and radiation dose rate fields during maintenance and shut-down periods. Neutronics today can accurately determine nuclear responses such as nuclear heating distributions for use in an integrated multi-physics approach (Sanz-Gozalo, private communication).

Significant progress has been made in the area of IFPP safety and environment over the past two decades. Focus has been driven toward the minimization of inventories, accident safety, development of safety guidelines and licensing considerations, and waste management approaches (El-Guebaly et al., 2004; Reyes et al., 2013a,b,c, 2016). An important inherent safety advantage of IFE when compared to magnetic fusion energy (MFE) concepts that have been proposed to-date (including ITER), is that loss of plasma control events with the potential to damage the first wall, such as disruptions, are non-conceivable, therefore eliminating a number of potential accident initiators and radioactive in-vessel source term generation. The main operating risks in a fusion nuclear facility relate to the presence of radioactive materials (tritium and activation products) that could conceivably be released to the environment following an accident. The hazards are primarily managed by the implementation of the main safety principles: as low as reasonably achievable (ALARA) and defense in depth. In this way, existing hazards are identified and maintained ALARA, and a confinement strategy is implemented based on multiple barriers to provide an appropriate level of protection, according to the level of risk.

When considering the construction and operation of a future fusion nuclear science facility or a DEMO (either IFE or MFE), it is recognized that much work needs to be done in the safety and licensing area. The US DOE Fusion Safety Standards (DOE-STD-6002-96, 1996; DOE-STD-6003-96, 1996) provide general safety requirements and guidance for fusion experimental facilities, such as the non-evacuation criteria used above. Nevertheless, these Standards were issued in 1996 and must be brought up to date to ensure the congruency with current regulations, and with expanded current understanding of fusion safety challenges. Regarding the ITER precedent set by the French regulator it is important to recognize that regulations developed for this first-of-a-kind tokamak in France may turn out to be overly conservative or simply inappropriate for practical application to next step fusion facilities. Potential key items that need to be examined/re-visited based on experience in ITER include load cases, acceptance criteria, safety margins, materials qualification approaches and the so-called beyond-design-basis (hypothetical) event requirements (Taylor and Cortes, 2014).

Table 5 In-vessel radioactive source term for ITER and various IFE designs (Reyes et al., 2016; Taylor et al., 2009; Reyes et al., 2001).

Mobilizable source term (kg)	ITER	HYLIFE-II	SOMBRERO	LIFE
In-vessel tritium	1	0.14	1.17	0.06
Activation products (material)	1000 (W)	0.5 (SS)	50 (C/C Composite)	13.9 (HT-9)

Furthermore, future fusion power plant operations will present different safety characteristics compared to current pulsed fusion experimental facilities such as ITER. It is also clear that the safety features of future IFE and MFE facilities could differ significantly, not only in those aspects related to the behavior of the plasma, but also in terms of amount of radioactive source term, available energy sources and potential initiating events. As an example, Table 5 gives a comparison of estimated accident source terms in various IFE facilities compared to ITER.

Initial safety studies indicate that hazards associated to a future IFPP can be appropriately managed. Simulation of worst-case scenarios indicate that the accident consequences are limited and that the potential release of radioactive material would remain below the limit for public evacuation (Reyes et al., 2016; Taylor and Cortes, 2014). It is recommended that future work continues to advance the design of the specialized equipment through experimental R&D in order to reduce existing technical uncertainties. The trade-offs between the tritium plant subsystems need to be carefully analyzed, and the design improved and optimized along the ALARA principle for tritium inventories, and the implementation of the confinement approach. Although the future licensing process for a commercial fusion facility is unclear at this stage, moving forward it will be important to develop and/or revisit fusion safety guidelines so that they are as congruent as possible with updated regulations and with current understanding of fusion safety challenges.

Technology for IFE fuel cycle and tritium control

A 2018 report by the Fusion Energy Science Advisory Committee (FESAC) on “Transformative Enabling Capabilities for Efficient Advance Toward Fusion Energy,” describes a series of transformative technologies toward fusion energy development, including advanced technologies for tritium fuel production, extraction, and processing. Here we describe the technologies that are relevant for the IFE fuel cycle.

The IFE fuel cycle has certain unique characteristics, like the use of only 1 mg of tritium per fusion target, limited target debris-wall interaction due to chamber gas protection schemes, and a high expected burn-up fraction ($\sim 30\%$), which impacts the design and operation of IFE tritium processing systems (Reyes et al., 2013a,b,c). These intrinsic features result in limited inventories inside the vacuum vessel and throughout the facility simplifying reprocessing requirements when compared to what has been traditionally proposed for MFE. Table 6 provides data showing the large differences between MFE and IFE as far as tritium on site for a given facility. For example, for an MFE demonstration power plant, the daily fueling rate is 13.6 times higher for MFE than for IFE. The tritium recovered from plant operations is 16.5 times higher for MFE than for IFE.

Regarding tritium inventories, pre-conceptual level designs of the complete IFE fuel cycle have previously been published according to the functional requirements and technology selection for each of the fuel cycle sub-systems (Reyes et al., 2016). These studies describe a path toward design optimizations and R&D efforts that could allow for substantial inventory reduction compared with traditional technologies. In particular, the IFE fuel cycle has been modeled using a chemical flowsheet designed to predict steady state tritium inventories using the Aspen simulation platform (LANL/SRNL, 2011). The IFE fuel cycle flowsheet was established to support estimating the effects of design modifications upon fuel cycle inventories and predicting the impact of alternate technologies. Simple models of process operations within each subsystem (e.g., diffusers, oxidizers, molecular sieve beds, etc.) were developed and moved in and out of the flowsheet to allow for these iterations. We emphasize that the results presented here are based on pre-conceptual level design assumptions and detailed models of process operations within each subsystem should be performed as the design matures. These assessments show the potential for large reductions in the plant tritium inventory by utilizing

Table 6 Example MFE and IFE fuel cycle parameters (Reyes et al., 2016).

Feature	ITER	MFE DEMO	IFE INTERIM	IFE DEMO
Fusion power (MWth)	500	2700	1200	2200
Fueling rate (kg/h)	1.1	1.0	0.03	0.06
Burn fraction (%)	0.3	2	23	27
T consumption (g/day)	76	412	169	366
T recovery (kg/day)	25.3	20.2	0.6	1
T breeding (g/day)	0.4	450	203	439

Note that the tritium consumption and recycling figures quoted for ITER assume that it is operating continuously (in the mode of the MFE DEMO quoted in the table). However, the real operational numbers would be smaller (the “as designed” duty cycle of the device once it is in its long-pulse operation mode is 25%, i.e. the ratio of fusion burn duration to the period between the start of each burn) (David Campbell, Private Communication).

technologies that have been proven on an experimental scale or are already under development and yet not fully commercialized, such as mini-TCAP (Andrievski and Khatchoyan, 2016), Palladium Membrane Reactors (PMRs) (Heung et al., 2011), and Cryogenic Viscous Compressors (CVCs) (Gallucci et al., 2013).

In particular, two systems showing significant inventory reduction potential are the Light Isotope Purification (LIP) and Isotope Separation (IS). The initial LIP design contained 83% of the total facility inventory due to the long regeneration time of the molecular sieve (MS) beds based on an over-simplified nearly spherical tank with desorption controlled by band heating on the tank exterior. The regeneration time of the MS beds would be greatly improved by simply optimizing bed geometry and the regeneration methodology. Furthermore, an even more significant tritium inventory reduction would be realized if the MS beds in LIP could be replaced by diffusers (typically palladium-silver alloy membrane permeators). Diffusers take advantage of the fact that molecular hydrogen can rapidly diffuse through palladium alloy membranes while other compounds are completely excluded (Heung et al., 2011). Diffusers do not include any significant quantity of condensed phases allowing for a reduction of over 90% in the LIP major equipment inventory. The Thermal Cycling and Adsorption Process (TCAP) in IS holds 10% of the total tritium inventory. The conventional TCAP consists of a Pd/K packed column and a plug flow reverser (PFR) column. Mini-TCAP replaces the PFR with an active column that provides the inverse isotopic effect of the palladium column doubling the process throughput while producing a higher purity raffinate in addition to the high purity product (Andrievski and Khatchoyan, 2016).

Finally, another possible design improvement has been identified in the Chamber Gas Handling (CGH) system, which purifies the xenon chamber gas for recycle into the chamber and recovers the unspent fuel. This initially was accomplished by passing a portion of the chamber exhaust through a series of condensers to first separate out compounds lighter than xenon (like water vapor, carbon dioxide, and methane), and then condense xenon from hydrogen and helium. Due to the cost of compression and the uncertainty in condenser design, the pre-conceptual design only processed 10% of the exhaust stream for fuel recovery. Currently under development for other fusion applications, Cryogenic Viscous Compressors (CVC) are tritium-compatible, single stage condensers that could handle the entire IFE chamber gas exhaust flow (Gallucci et al., 2013). Designed to condense molecular hydrogen from helium, CVCs could more readily handle the requirements for Xe purification and recycling and tritium recovery. Future work will focus on additional optimization and design iteration, with the goal of advancing the design toward the conceptual stage. Trade-offs between the tritium plant subsystems need to be carefully analyzed, and the design improved and optimized along the ALARA principle for tritium inventories, and the implementation of the confinement approach.

Technology for IFE thermal management and electrical power production

There are different proposed options for heat extraction materials to support electrical power production for IFPPs. The option that shows the greatest thermal to electric conversion efficiency is the Brayton cycle with superior performance over Rankine cycles used in current nuclear power plants.

Different blanket materials can flow to create the primary coolant cycle of the power plant. There could be two main blanket material coolant states: a gas or a liquid. The gases He or CO₂ are used in IFPP concepts as well as Li₁₇Pb₈₃ and FLiBe or FLiNaBe coolants for liquids. Lithium must be a main constituent of the blanket in either a liquid form or in a ceramic solid form. Gas would flow through this media confined to tubes for flow purposes and to extract heat. The IFPP concepts LIFE, HiPER and KOYO-F chose to use Li as a liquid metal coolant.

The thermal deposition and management in the power plant cycle of the European HiPER concept is discussed here in detail (Sanchez et al., 2013). Technologies available in the short term were considered and studied to minimize risks. For the HiPER reactor proposal, the option of a self-cooled lead lithium (SCLL) blanket was proposed and two different arrangements of first wall (FW) cooling were laid out: an integrated first wall-blanket (IFWB) and a separate first wall-blanket (SFWB). In the IFWB configuration all the fusion energy of the reactor is extracted with a single coolant (Li₁₇Pb₈₃) whereas in the SFWB there are two different coolants, one cooling the FW (He) by removing about 20% of the energy and the other cooling the blanket (Li₁₇Pb₈₃) removing the remaining 80% of the energy. A simple ideal helium Brayton power cycle was analyzed for both IFWB and SFWB options in order to compare them in terms of power cycle efficiency. The SFWB yielded a higher thermal to electrical conversion efficiency than IFWB so we examine this design more closely (Sánchez, 2011).

In the IFWB, the Li₁₇Pb₈₃ carries to the outside of the reaction chamber all of the energy deposited in the blanket and first wall, a thermal power of 1702.5 MW. Thus, the cold and hot temperatures of the Li₁₇Pb₈₃ loop, 350 °C/450 °C is the operating temperature window for the power cycle. It is worth remembering the origin of these limits. When irradiating EUROFER97 below 350 °C, it suffers radiation induced hardening and a DBTT shift above room temperature. EUROFER97 is a ferritic/martensitic steel with reduced activation properties that has good thermo-mechanical properties and good dimensional stability under irradiation (i.e., resistance to swelling) (De Meis and Mazzone, 2016). On the other side, above 450 °C, the corrosion rates of the Li₁₇Pb₈₃ with EUROFER may become unaffordable. If the corrosion rates were exempt, the upper temperature limit would be 550 °C. Above that, the EUROFER97 suffers from creep rupture.

The SFWB configuration, as mentioned, makes use of a helium branch from the secondary circuit to cool the first wall independently from the blanket so here there are two heat sources. The helium Brayton power cycle for the SFWB layout is shown in Fig. 31. In this case, the first wall receives 25% of the fusion energy and the blanket 75%.

In addition to the heat magnitude difference, the heat sources operate at different temperatures. The blanket temperature range is, as was the case of the IFWB, 350 °C/450 °C. However, the first wall, being exempt from Li₁₇Pb₈₃, does not present any corrosion threat. If the first wall was built out of EUROFER97 protected with aluminum coatings, the upper temperature, 450 °C could be

Fig. 31 HiPER power plant cycle schematic (Sanchez et al., 2013).

raised to 550 °C, or this purpose, the use of ODS-EUROFER97 could be justified (ODS stands for Oxide Dispersion Strengthened). The creep rupture threat of the ODS-EUROFER97 starts at 650 °C and the radiological performance is the same as EUROFER97. It is remarkable that the ODS-EUROFER97 makes sense as structural material only for an independently cooled first wall, as the upper temperature in the blanket is limited to 450 °C for corrosion reasons. Then, in the SFWB configuration, there are two heat sources: the first one is 375 MW operating at 350 °C/650 °C, and the second one is 1327.5 MW operating at 350 °C/450 °C. In this study, a simple helium Brayton cycle is designed, making use of the same basic cycle scheme for the more efficient SFWB case, in order to compare power cycle efficiencies when adding inter-cooling and re-heat processes.

The power cycle diagram is shown in Fig. 31. The following assumptions are made for the SFWB power cycle analyses considering additional inter-cooling stages and a re-heating process step as in nuclear power plants.

The inputs to the data analyses included $\text{Li}_{17}\text{Pb}_{83}$ coolant inlet/outlet temperatures of only 350/450 °C limited to this rather low value by effects to the first wall structural material, helium pressure of 8 MPa, inlet helium temperature to both compressors of 30 °C, reactor thermal power of 1702.5 MW and the coolant temperatures inlet and outlet for the first wall of 350/650 °C. Further, pressure drops in pipelines, in junctions, and in flow splitting were not considered. Pressure drops were considered across intercoolers, recuperator, heat exchanger and cooler. Changes in kinetic and potential energies in each component were neglected. The turbines isentropic efficiency was assumed to be 93% with 90% for the compressors. Recuperator and heat exchanger effectiveness were considered to each be 95%.

The results showed that for the optimum compression ratio of 1.8 the maximum conversion efficiency was 35.3%. However, with a re-heat cycle, the efficiency was raised to 37% and if a rise of 100 °C could be achieved for the outlet coolant temperature, for example, by using Al plating on EUROFER97, then the efficiency could reach 42.5% (Sánchez, 2011).

Future technologies

Some exciting new technologies are going to make a major impact on the development and successful implementation of Inertial Fusion Power. These include Additive Manufacturing, Artificial Intelligence, and Machine Learning and are described further below.

IFE and additive manufacturing

Fusion introduces many materials science challenges related to the behavior of tritium, the effects of the build-up of He and hydrogen, and the effects of displacements per atom (dpa) on lattices for strength and other properties—among many others. Additive manufacturing, which makes parts from three-dimensional models typically in layer-by-layer “builds,” could make major contributions to fusion systems (Nygren et al., 2018) in a similar way it is making major contributions in many industries today such as making jet engines (Dutta and Sam Froes, 2015). Fig. 32 shows five examples of products made from Metal Additive Manufacturing (MAM) that suggest that some crossover into fusion applications may be possible—especially for thick parts that are used in a fusion chamber. AM is excellent for making complex shapes, like enclosed void spaces as for coolant channels, and for when novel materials are used requiring jointless transitions from one material to another. Fabrication of refractory metals without melting may mitigate issues such as distortion, residual stresses, and crack formation in large structures. AM can also include processes called Direct Write where an example is depositing a thick slurry (ink) to build a fragile “green” preform that can be machined easily and then cured later to gain its finished properties. AM and Direct Write and similar processes are together known as AM+. The reference (Nygren et al., 2018) provides 45 references that cover a broad range of applications of AM that could have use of benefit for fusion.

Fig. 32 Some AM metal products are shown and the method to produce them described: (a) TiC-Ferritic-Martensitic Steel preforms made by the binder jet process (Levy et al., 2017); (b) W Multi-pinhole collimator, made by selective laser melting (Deprez et al., 2013); (c) Ti turbine blade made by e-beam (Dutta and Froes, 2018); (d). W complex shape made by e-beam (Hancock et al., 2017); (e) Inconel 718 engine mount made by direct metal laser sintering (Hazeltine, 2009).

Nygren goes on to suggest specific contributions AM could make to fusion:

Features that may be useful for Plasma Facing Components (PFC) and that AM+ can easily provide include controlled porosity, functionally graded materials, and complex cooling channels. Enabling designs with a fine array of cooling jets for PFCs is one example. Another is controlled porosity or other nano-features (micro-fibers and/or nanoparticles) in the region of material close to the plasma-facing surface. Such features might increase recombination and recycling of D/T or mitigate crack growth into the deeper structure (an identified concern for W-based PFCs). Features that can collect He and transmutation products and limit tritium trapping, as well as graded compositions and transitions in materials may be important in developing PFC solutions and their development paths (Nygren et al., 2018, p. 2).

In tritium breeding blankets, most programs give solid breeders a higher priority for R&D than liquid breeders (e.g., Li or Li-Pb). Solid breeders are typically ceramics with relatively poor thermal conductivity arranged in pebble beds. AM+ offers the possibility to make open porous structures that could offer much improved performance for tritium breeding blankets and eliminate issues such as compaction in pebble beds. Also, with a radially graded structure, adjusting the breeder fraction and the cooling to the gradients in the nuclear heating and tritium production would be possible. A standard pebble bed design would require additional structure to make separate zones (Nygren et al., 2018, pp. 2–3).

Youchison and Garde (2012) have made open porous structures such as (d) in Fig. 33 and has modeled details of the flow and heat transfer and also fabricated open celled structures using ceramics. Manifolds and shielding could also be supported by AM+. Load pads for cryogenics could also be made for robustness under high mechanical loads while providing thermal isolation by using layers that transition from load bearing to thermally isolating. Large parts could be re-envisioned as collections of smaller parts giving more flexibility in design approach, a reduced volume of special shapes needed, and a reduction in the volume of replacement parts.

AM+ may provide solutions at lower cost than alternative options for some fusion applications but fusion engineers also need to keep in mind that AM “is rife with mega-hype and overblown promises.” “Many would-be users view AM as a silver bullet to fix all. Fortunately, AM experts can easily advise where AM can be useful and where it is not” (Nygren et al., 2018, p. 3).

Fusion engineers also need to be aware that the benefits of AM may require an R&D effort to be realized if other applications have not developed the material or fabrication process needed. Early consideration of AM and engagement with AM engineers can identify R&D pathways for those applications seen as feasible and enable the development of an AM Roadmap.

IFE and artificial intelligence and machine learning

Artificial Intelligence (AI) is the theory and development of computer systems to be able to perform tasks that normally require human intelligence such as decision-making. Closely coupled is machine learning where a computer program can learn and adapt to new data without human intervention. Machine Learning (ML) is a field within artificial intelligence that keeps a computer’s

Fig. 33 AM parts for made for fusion (a–c) (Hancock et al., 2017); (d) Mo ligament structure formed in CVD (Youchison and Garde, 2012).

built-in algorithms current regardless of changes in its environment. A complex algorithm or source code is built into a computer that allows for the machine to identify data and build predictions around the data that it identifies. Machine Learning is useful in parsing the immense amount of information that is consistently and readily available in the world to assist in decision making. Machine Learning is being applied in a variety of areas and here we discuss applying it to the operations of an IFPP. Deep Learning (DL) is a subset of machine learning applications that teaches itself to perform a specific task with increasingly greater accuracy, without human intervention, and will also be very useful in an IFPP setting.

There will be many highly precise and highly repeatable functions that take place inside an IFE power plant. Then net fabrication of targets will need to be conducted very rapidly, perhaps 5–10 per second, in the IPFF Target Fabrication Facility. This will require a number of target fabrication stations working in unison to meet the local target demand. The tolerances are sub-micron on dimensions meaning that this rapid process must also be very precise. The process will need to be fully automated. Each target will need to be highly mensurated during its fabrication process through the use of highly precise and optimized sensors. The overall feedback and control relying on AI/ML/DL will be required for successful performance. To further complicate the process, the fabrication step that mates materials to the target capsule will need to be done at cryogenic temperatures. The target capsule fabrication and cryogenic filling step will also be done using AI/ML/DL processes combined with robotics. The current movement toward “lab-on-a-chip” at LLE for target fabrication is also a natural setting to implement robotics, machine learning, and artificial intelligence leading to accurate, precise, rapid, and economic target fabrication.

The transport/delivery of the target to the target injection station will need to be done where further sensor outputs allow the AI/ML/DL system to ensure that the target stays at the right temperature (18 K) with no more than 0.5 K fluctuation and with exquisite control over the robotic system providing the transportation.

The target will need to be properly positioned within the target injection system and integrated into the chamber processes seamlessly such that it does not experience any deleterious heating due to chamber emissions. The target, designed to robustly withstand the acceleration processes and housed in a sabot, is then accelerated at the right instant to within less than a tenth of a second to enter the chamber. Systems relying on AI/ML/DL will continually “sense” the chamber conditions to ensure they are suitable for target insertion.

Once inserted, the AI/ML/DL system is continually aware of the target position, the removal rate of any attached sabot, and the timing and coordination of all beamlines of energy that need to adjust to the predicted irradiation location in the chamber such that the irradiation takes place to within tens of microns in a chamber meters in diameter. This could only be done using AI/ML/DL systems to control the mechanical and electrical systems performing the functions.

The emissions of the target will also be diagnosed and the knowledge the AI/ML/DL systems has acquired will allow it to very accurately predict when chamber clearing will have occurred to keep the timing of targets into the chamber synchronized so that targets robustly survive to chamber center.

Advanced algorithms will be the backbone of machine learning systems and transform our vision of feedback control for a IFPP. This will enable operation at optimized operating points whose achievement and sustainment are impossible without high performance feedback control. The area of advanced algorithms includes the related fields of mathematical control, machine learning, artificial intelligence, integrated data analysis, and other algorithm-based R&D. Given the pace of advances, control solutions that establish IFPP operations will become within reach, as will the discovery and refinement of physics principles embedded within the data from experiments at current facilities such as NIF, Omega, and LMJ.

In February 2018, the Department of Energy's Office of Science published a report by the Fusion Energy Sciences Advisory Committee on Transformative Enabling Capabilities for Efficient Advance Toward Fusion Energy. While the report only examined Transformative Enabling Capabilities (TEC) for magnetic fusion energy, many TECs identified in the report were equally applicable to inertial fusion energy such as Advanced Algorithms and its comments on Artificial Intelligence (AI) and Machine Learning (ML) (DOE, FESAC, 2018).

The Report on Advancing Fusion with Machine Learning Research Needs Workshop held April 30–May 2, 2019, by FES and ASC stated:

Science Discovery with Machine Learning involves bridging gaps in theoretical understanding via identification of missing effects using large datasets; the acceleration of hypothesis generation and testing and the optimization of experimental planning. Essentially, machine learning is used to support and accelerate the scientific process itself.

Machine Learning Boosted Diagnostics is where machine learning methods are used to maximize the information extracted from measurements, systematically fuse multiple data sources and infer quantities that are not directly measured. Classification techniques, such as supervised learning, could be used on data that is extracted from the diagnostic measurements.

Model Extraction and Reduction includes the construction of models of fusion systems and the acceleration of computational algorithms. Effective model reduction can result in shorten computation times and mean that simulations (for the tokamak fusion reactor for example) happen faster than real-time execution.

Extreme Data Algorithms involves finding methods to manage the amount and speed of data that will be generated during the fusion models.

Data-Enhanced Prediction will help monitor the health of the plant system and predict any faults, such as disruptions which are essential to be mitigated.

Fusion Data Machine Learning Platform is a system that can manage, format, curate and enable the access to experimental and simulation data from fusion models for optimal usability when used by machine learning algorithms (DOE, Report on ML, 2019, pp. 2–3).

Data science methods from the fields of machine learning and artificial intelligence offer opportunities for enabling or accelerating progress toward the realization of fusion energy by maximizing the amount and usefulness of information extracted from experimental and simulation output data.

Magnetic fusion energy research is working very hard to try to use AI/ML techniques to try to solve one their most intractable problems—predicting when disruptions will occur and be able to mitigate or prevent their occurrence to prevent damage to Plasma Facing Components. Inertial fusion energy does not have an analogous problem to solve but the solution by magnetic energy researchers may provide insight into addressing IFPP-related control issues.

The collaborative development of the sensors and data collection system coupled with the Artificial Intelligence and Machine Learning/Deep Learning techniques are critical research activities in the near future to realize Inertial Fusion Energy.

Glossary

Direct-drive An ICF approach for which the driver energy is directly applied to the target.

High energy density plasma (HEDP) High energy density plasma is a plasma in which the internal energy density exceeds 1 Mbar of pressure.

Ignition The condition for which the energy deposition from thermonuclear reaction products within a volume of plasma is sufficient to maintain the plasma temperature and fusion reactivity in the absence of external heating.

Indirect-drive An ICF approach in which the driver energy is first converted to secondary energy such as thermal X-rays which then compress a target.

Inertial confinement fusion Fusion concept in which energy is delivered to the outer surface of a target, initiating an inward implosion. The imploding target compressionally heats fusion fuel located within an inner cavity. Inertia of the imploding mass is used to confine the thermonuclear-burning gas.

Pulsed-power The application of the rapid discharge of energy to generate large electrical current.

Introduction

All inertial confinement fusion (ICF) approaches rely on compression of the fusion fuel to increase the fuel density and temperature¹ towards the initiation of fusion self-heating, thermonuclear burn, and energy gain. ICF concepts systematically rely on generating large fuel pressures to maintain thermonuclear self-heating rates in excess of the net power lost by the gas from various processes, making them inherently pulsed and not steady state systems. Furthermore, ICF designs rely on three principal methods for compression and heating: light (either optical or X-ray) generated ablation pressure, electro-magnetic forces, and particle-beam (electron or ion) heating.

The earliest laboratory ICF experiments compressed hot plasma using magnetic fields to “pinch” (or stagnate) the plasma along a particular axis (e.g., Z-pinch, theta-pinch, screw-pinch, etc.). These approaches were unsuccessful as a result of various plasma instabilities that limited the achievable plasma densities, temperatures, and energy-confinement-times,² limiting fusion energy production.

¹Some concepts include additional external heating sources in the form of photons or particles.

²The energy-confinement-time for a thermonuclear plasma is the time-scale on which the global energy density changes as a result of various cooling mechanisms.

The demonstration of the laser in 1960 revolutionized the pursuit of inertial confinement fusion as it provided a potential means to directly compress the fuel to the extreme densities and temperatures necessary to generate significant fusion reactions, using only the inertia of the system for energy confinement (Nuckolls et al., 1972). Since that time, the laser has played a significant and dominant role in the development of inertial fusion energy (IFE). In addition to directly applying the laser energy to the compression of the target, commonly referred to as laser-direct-drive (LDD) (Craxton et al., 2015), the energy in the laser can also be converted to X-ray drive pressure, using a hohlraum (Lindl, 1995; Lindl et al., 2004), to compress the target. This indirect compression approach is commonly referred to as laser-indirect-drive (LID) and is the most developed approach to inertial fusion being pursued today. Additionally, alternative approaches apply both a long-pulse laser to compress the fuel to high density followed by a short-pulse (< 10 PS), high-intensity ($> 10^{18}$ W cm $^{-2}$), peta-watt lasers (Danson et al., 2019) to generate particle beams of protons or electrons that are then delivered to the hot deuterium-tritium (DT) gas in the center of the target to provide additional collisional heating to the gas in order to initiate thermonuclear ignition of the fusion fuel (Tabak et al., 2005). These “fast ignition” concepts require the co-location of both a target compression driver and a particle-beam source.

Along with laser systems, other dominant inertial fusion drivers include pulsed-power, or magnetic drive systems, as well as heavy-ions. While early magnetic-drive (or pinch) concepts were limited by magnetohydrodynamic instabilities, today’s systems are substantially more advanced, powerful, and diverse in their utility and application (Sinars et al., 2020). Today, magnetic drive is being used to study both indirect-drive target concepts (Sanford et al., 1999; Cuneo et al., 2012; Olson et al., 2020) as well as magnetic-driven concepts that also exploit laser heating and externally applied magnetic fields (Slutz and Vesey, 2012). As no implosion system coupling heavy-ion driver energy to an inertial fusion target exists today, heavy ion fusion research continues to work towards independently establishing control and conditioning of the ion beams themselves (Hofmann et al., 2018).

In addition to being uniquely configured and scaled for ICF implosions and the development of IFE, today’s major inertial fusion facilities have also led to the emergence of high-energy-density (HED) physics as a scientific frontier in the field of plasma physics. Today’s generation of major ICF facilities field experimental platforms³ that deliver the most extreme states of matter on Earth, and produce an ever increasing number of breakthrough discoveries ranging from the formation of exotic material states only found in the cosmos, such as metallic hydrogen (Celliers et al., 2018) and diamond rain (Kraus et al., 2017), to the self-generation of magnetic fields from turbulent dynamo processes (Tzeferacos et al., 2018) believed to play a prominent role in establishing the intergalactic magnetic field.

While laser and pulsed power-based facilities comprise the major implosion facilities in ICF today, in the past two decades there has also been significant development in alternative inertial confinement concept drivers and approaches (Thio et al., 2001), and new investments from private sector start-ups are increasingly exploring alternative instrument configurations. These new alternative concept approaches are not yet at a scale that could be consider “major” and as such are not reviewed here.

This article discusses the major experimental inertial confinement fusion facilities both in use today and under development. Major inertial confinement fusion facilities are defined as: laser facilities capable of delivering 10 kJ or more of energy to an imploding fusion target, and pulsed-power facilities capable of providing a main load current greater than 5 MA. Additionally, this article focuses on facilities and not experimental programs such as MAGO/MTF (Chernychev et al., 2016; Chernyshev et al., 2018) that, while satisfying the current criteria for pulsed power systems, are not executed using a fixed facility capability. Here, they are organized by driver technology, principally laser and pulsed-power facilities.

Laser facilities

The only “ignition”-scale facilities operational today are laser-based instruments such as the National Ignition Facility (NIF) at Lawrence Livermore National Laboratory in Livermore, CA, United States. Laser based ICF facilities are generally configured, with regard to laser injection orientation around the central target chamber, to support a specific LDD or LID target concept. Here, the major laser drivers for ICF are reviewed and listed in Table 1.

The National Ignition Facility (Livermore, CA, United States)

The National Ignition Facility (NIF) at Lawrence Livermore National Laboratory in the United States is the world’s most energetic laser, capable of delivering more than 2 MJ of energy onto a target with a peak power of 500 TW. Plans for the construction of the NIF began in 1993 (Paisner et al., 1994, 1995), with the official ground-breaking occurring in 1997, and the facility was completed in 2009. Following completion, the National Ignition Campaign (NIC) was initiated to develop and integrate all capabilities required for pursuing fusion ignition and, if possible, to demonstrate fusion ignition and energy-gain by the end of 2012 (Lindl et al., 2014). While fusion ignition remains elusive and has yet to be achieved on the NIF, researchers continue to make progress (Hurricane et al., 2019) with the NIF holding the record for having achieved the highest laboratory inertial fusion neutron yields to date at $\sim 3 \times 10^{16}$. Today, NIF remains the only mega-Joule class laser ICF facility in the world, fields in excess of 400 experiments

³A “Platform” is a unique experimental hardware set/configuration for the generation and study of the formation and dynamics of a particular state of matter, including integrated implosions.

Table 1 List of major laser ICF facilities worldwide.

Facility	Location	Systems/type	# Beams	Configuration	Key parameters (energy/time/wavelength)	Status
NIF	United States	NIF/Nd:glass	192	Polar/4 cones	2.2 MJ/4 ns/351 nm	Operational
		ARC/	4		0.4 kJ/1.3 ps/1053 nm	Operational
LMJ	France	LMJ/Nd:glass	176	Polar/2 cones	1.5 MJ/4 ns/351 nm	40 Beams operational
		PETAL/Nd:glass			0.85 kJ/0.7 ps/1053 nm	Operational
UFL-2M	Russia	UFL-2 M/Nd:glass	192	Symmetric	2.8 MJ/tbd/527 nm	Under construction
SG-III	China	SG-III/(Yb-fiber, Nd:glass)	48	Polar/4 cones	180 kJ/3.5 ns/351 nm	Operational
Omega	United State	Omega-60/Nd:glass	60	Symmetric	40 kJ/0.8 ns/351 nm	Operational
		Omega-EP/Nd:glass	4		0.5 kJ/0.7 ps/1053 nm (5 kJ/351 nm)	Operational
Iskra-5	Russia	Iskra-5/iodine	12	Symmetric	30 kJ/0.3 ns/1316 nm	Operational
					2.6 kJ/5 ns/657.6 nm	Operational
SG-II UP	China	SG-II UP/Nd:glass	8	Polar/1 cone	24 kJ/3 ns/351 nm 1 kJ/	Operational
		SG-II PW/Ti:sapphire	1		1.7 ps/1053 nm	Operational

		LFEX/Nd:glass	4		2.8 kJ/1 ps/1053 nm	Operational

annually, and continues to serve as a key element of the National US Nuclear Security Administration's science-based Stockpile Stewardship Program. Images of the NIF are shown in Fig. 1.

The NIF is a flash-lamp pumped neodymium (Nd) glass (Nd:glass) laser, capable of producing up to 20 kJ of energy in each beam at the fundamental (1ω) wavelength of 1053 nm (infrared) (Moses et al., 2008). The system consists of 192 individual beams that are transported in groups of four, called "quads," to the target chamber where the beams in each quad are frequency tripled (3ω) to the wavelength of 351 nm (ultraviolet). After frequency conversion to 3ω , each beam has approximately 10.5 kJ of energy. The beams are focused through a final focus lens onto the target at target-chamber-center (TCC), delivering up to 2.2 MJ of total energy in a temporally shaped pulse with peak power of approximately 500 TW.

The NIF is currently configured for research on LID fusion concepts that convert the incident laser light using cylindrical hohlraums to X-ray drive pressure for compressing the fusion fuel (Lindl et al., 1995, 2004). As a result, the 48 final optics assemblies that house each quad of beams are positioned around the top and bottom poles of the target chamber in 4 cones at polar angles 50 degrees, 44.5 degrees, 30 degrees, and 23.5 degrees. The target chamber is a 10 m diameter, 10 cm thick aluminum vessel, designed specifically to withstand a 45 MJ yield output, 1200 MJ annual-yield, and 50 shots of 20 MJ per year (Paisner et al., 1994). The vessel contains 48 indirect-drive ports, 24 direct-drive ports, and 85 diagnostic ports. The additional direct-drive ports allow for the modification of the NIF to accommodate a symmetric laser-direct-drive configuration.

Each beam within a quad can be steered individually, enabling each beam to be precisely positioned with regard to the target. Providing a further level of control, the NIF also has the capability to tune the wavelength of the laser beams by approximately ± 2.3 Å. At present, the NIF laser has the capability to do this with three separate wavelengths simultaneously, one wavelength for each of the inner beam cones (23.5 degrees and 30 degrees) and one for all of the beams in the outer cones (44.5 degrees and 50 degrees). NIF beam also employ Random phase plates and limited smoothing by spectral dispersion to improve on target beam quality.

Additionally, the NIF laser provides a great deal of flexibility in pulse length and laser pulse shape. The NIF has the capability to deliver a variety of precision laser pulse shapes. Each quad may be independently configured for both timing and laser pulse shape, with the shape and timing of a pulse being common for all four beams within a single quad. As a result of the amplifier configuration, the flexibility of the pulse shaping is limited between the two quads within a single bundle.

Fig. 1 (A) Image of the NIF laser-bay. (B) Image of the NIF target chamber. (C) Image of the inside of the NIF target chamber including target position. Image (A) <https://www.flickr.com/photos/lnl/3676978870/in/album-72157607099824019/>; (B) <https://www.flickr.com/photos/lnl/3421927305/in/album-72157607099824019/>; (C) <https://www.flickr.com/photos/lnl/3421902499/in/album-72157607099824019/>

Targets are held and positioned by either cryogenic or non-cryogenic TARget POSitioners (TARPOS), see Fig. 1C. For ignition targets, a Cryo-TARPOS is necessary to complete the formation of the fuel ice layer within the target as deuterium-tritium fuel is transferred to the capsule, using temperature differentials, through the capsule fill-tube. Beta-layering⁴ is used to ensure a smooth inner ice surface within the capsule (Moses, 2008).

The NIF hosts a wide array of some of the world's most advanced diagnostics for evaluating HED systems, and indirectly-driven ICF implosions, in particular. These include, but are not limited to, full aperture backscatter for hohlraum energetics, velocity interferometers for shock timing, calibrated soft X-ray spectrometers to measure radiation drive, gamma ray detectors to measure burn history, and a magnetic recoil spectrometer to measure neutron spectra. Further information regarding the NIF diagnostics is available on the NIF website [<https://lasers.llnl.gov>].

In addition to the 192 long-pulse drive beams, the NIF also hosts the ARC (Advance Radiography Capability) laser (Di Nicola et al., 2015). The ARC laser uses four beams (1 quad), each beam being split into two, producing a total of 8, petawatt (PW) class beams delivering between 0.4 kJ and 1.7 kJ in 1.3 ps and 38 ps respectively. As such, the NIF ARC can provide high-energy X-ray energies for radiographic imaging using the backlighting technique. By staggering the delivery timing for each of the eight beams onto a backlighter target, the NIF ARC system can deliver a time-sequence (i.e., movie) of radiographic images showing the evolution of target materials and the core through the implosion.

Laser Mega-Joule (Le Barp, France)

The Laser Mega-Joule (LMJ) was developed by the Commissariat à l'Energie Atomique et aux Energies Alternatives (CEA) and is located at the Centre d'études scientifiques et techniques d'Aquitaine (CESTA) in Le Barp, France. Construction on the LMJ was started in 2003 and continues today. In addition to serving as a frontier instrument for the study of HED science and ICF, the LMJ is part of the French Simulation Program to improve physics models through experimental validation of high-performance numerical simulation (Miquel et al., 2016). The current design for the LMJ is to deliver a total of 1.4 MJ of energy with a peak power of 400 TW to a fusion target using 176 laser beams. At present, 40 of the planned 176 beams have been commissioned and are operational (Nicolaizeau and Miquel, 2019). Images of the LMJ facility are found in Fig. 2.

Similar to the NIF laser in the United States, the LMJ laser is a flash-lamp pumped, Nd:glass laser producing 15 kJ of energy per beam at the fundamental (1ω) wavelength of 1053 nm. The beams are organized into "bundles" of eight beams that are divided into two quads (four beams per quad). Each quad is transported to the target chamber where it enters the frequency conversion and focusing system (SCF) (Nicolaizeau and Miquel, 2019). Within the SCF, each beam is frequency tripled to 3ω , or 351 nm, and focused to TCC using the 3ω focusing grating. After frequency conversion to 3ω , each beam has approximately 9 kJ of energy. Like the NIF, LMJ will use both cryogenic and non-cryogenic target positioning systems to hold and position targets at TCC (Miquel et al., 2016).

LMJ is configured for experiments supporting laser-indirect-drive concepts, with the beams being positioned in cones in the upper and lower hemispheres of the target chamber. The target chamber is a 10 m diameter, 10 cm thick aluminum sphere containing 200 ports for both laser injection and diagnostics. Forty quads will enter the target chamber through ports located on the two cones at 33.2 degrees and 49 degrees polar angles. The other four quads will be positioned at a polar angle of 59.5 degrees for

Fig. 2 (A) Image of the inside of the LMJ target chamber. (B) Cartoon schematic depicting implementation of the PETAL laser. Image (A) <https://www.science-et-vie.com/archives/laser-mega-joule-la-nouvelle-arme-de-dissuasion-nucleaire-40582>; (B) Nicolaizeau M and Miquel JL (2019) LMJ status: Fifth bundle commissioning and PW class laser coupling. In: *Proceeding of the SPIE 10898, High Power Lasers for Fusion Research* vol, 1089802 (4 March 2019). doi: <https://doi.org/10.1117/12.2507193>.

⁴Beta-layering occurs in a hot-spot filled with DT and cooled below the triple point. Self-heating due to the absorption of beta particles redistributes solid matter as a net sublimation of material from thick to thin regions takes place (Miller, 1976).

radiography (Miquel et al., 2016). The LMJ laser is capable of providing sophisticated, ignition-design-relevant laser pulse shapes having a minimum duration of 0.7 ns and maximum duration of 25 ns. Furthermore, as with the NIF, complex shapes such as a rising pulse, decreasing pulse, multiple pulse, with pedestal, etc. are possible (Casner et al., 2015).

An array of various photon and particle diagnostics are being considered and developed for LMJ. These include, but are not limited to, hard (keV) and soft (100's eV) X-ray imaging systems, a calibrated X-ray spectrometer, VISAR,⁵ Streaked Optical Pyrometer, a full aperture backscatter system, etc. To date, nine plasma diagnostics have been deployed and commissioned (Nicolaizeau and Miquel, 2019).

In addition to the long-pulse, compression lasers, the LMJ facility also hosts PETAL (PETawatt Aquitaine Laser). PETAL is short-pulse (500 fs to 10 ps), ultra-high-power (> 1 PW), high energy (> 1 kJ) laser. The PETAL design incorporates a mode-locked titanium-sapphire (Ti:sapphire) oscillator front end, and is based on chirped pulse amplification (CPA) combined with optical parametric amplification (OPA) (Nicolaizeau and Miquel, 2019). The PETAL beams are synchronized with the main LMJ lasers, and are injected in the equatorial plane of the LMJ target chamber using an off-axis parabolic mirror. The system was commissioned in 2015 with a performance of 1.15 PW, 700 fs, yielding 850 J. PETAL represents a significant capability for the LMJ facility as it extends the facility's diagnostic capabilities. Furthermore, LMJ-PETAL is open to research by members of the academic communities for 20–30% of the facility operating time, providing a rich resource for a wide array of HED science applications, particularly in laboratory astrophysics (Casner et al., 2015). Since 2014, more than 300 experiments have been fielded using LMJ and PETAL.

UFL-2M (Sarov, Nizhny Novgorod, Russia)

In 2012, the construction of the UFL-2M was initiated at the Russian Federal Nuclear Center, All-Russian Scientific Research Institute of Experimental Physics (RFNC-VNIIEF) in Sarov, Nizhny Novgorod, Russia. The UFL-2M facility is designed and scaled to achieve laboratory fusion ignition by delivering 2.8 MJ of laser energy onto a target using 192 beams (Rozanov et al., 2016). Unlike the NIF and LMJ, the UFL-2M facility will be configured for geometrically symmetric illumination of a target, accommodating the pursuit of direct-drive ignition concepts as well as spherical-indirect-drive designs.

The UFL-2M laser will be a Nd:glass laser, delivering 12.5 kJ per beam at the second harmonic (2ω), or 527 nm, an important distinguishing characteristic from NIF to LMJ, which use 3ω light. Completion and commissioning of the facility is anticipated in the first half of the 2020 decade (Rozanov et al., 2016).

Shen-Guang III & IV (Mianyang, China)

The Shen-Guang III (SG-III) laser is located at the Laser Fusion Research Center (LFRC) of the China Academy of Engineering Physics (CAEP) in Mianyang, China. SG-III is the largest laser ICF facility in China, consisting of 48 beams capable of delivering a total of 180 kJ, 60 TW of power, at 351 nm in 3.5 ns (Zheng et al., 2016). Construction of SG-III was initiated in 2007 and completed in 2015. SG-III was developed specifically for ICF studies (Jiang et al., 2019) in China. Images of the SG-III facility are found in Fig. 3.

Fig. 3 (A) Image of the target area for the Shen-Guang III laser. (B) Image of the laser bay for the Shen-Guang III laser. Image Lan K et al. (2016) Progress in octahedral spherical hohlraum study. *Matter and Radiation at Extremes* 1(1): 8–27. doi: <https://doi.org/10.1016/j.mre.2016.01.003>.

⁵VISAR stands for Velocity Interferometer System for Any Reflector and measures the relative speed of a moving surface by recording its Doppler wavelength shift.

SG-III is a Yb-fiber seeded, Nd:glass laser produces 7.5 kJ of energy per beam at the fundamental (1ω) wavelength of 1053 nm (Zheng et al., 2008). The beams are transported to the target chamber, where the final optics assembly frequency triples the beams to 3ω , or 351 nm. After the frequency is tripled to 351 nm, each beam has approximately 3.2 kJ of energy. The SG-III laser systems have a pulse shaping capability for delivering ignition-design-relevant laser pulse shapes. Additionally, smoothing of the beams using a continuous phase plate (CPP), smoothing by spectral dispersion (SSD), and polarization smoothing (PS) have all been adapted (Zheng et al., 2016).

SG-III is principally configured to support research on indirect-drive target concepts. The beams are arrayed around the top and bottom of the target chamber surface in four cones having polar angles of 28.5 degrees, 35 degrees, 49.5 degrees, and 55 degrees (Lan et al., 2016). The target chamber is 6 m in diameter. The SG-III laser facility has in excess of 80 diagnostics (Jiang et al., 2019). These diagnostics include, but are not limited, to: soft X-ray spectrometers, transmission grating spectrometers, 4ω Thompson scattering imaging system, full aperture backscatter diagnostics, and optical diagnostic systems such as VISAR. For a more complete listing, see Ref. (Wang, 2020).

The Shenguang-IV laser has been proposed with an initial design goal of achieving 1.5 MJ or greater energy. While the design for SG-IV has yet to be finalized, the intention is for the facility to demonstrate the achievement of fusion ignition. Initial design concepts of the target chamber is to enable spherical illumination (He and Zhang, 2013; Zheng et al., 2008).

Omega (Rochester, NY, United States)

The Omega laser facility is located at the University of Rochester's Laboratory for Laser Energetics (LLE) in Rochester, NY, United States. The facility hosts both the Omega-60 and Omega-EP laser systems. The Omega-60 laser was last upgraded in 1995 (Soures, 1991; Boehly et al., 1995), while the Omega-EP system was completed in 2008 (Waxer et al., 2005). The Omega laser facility plays an important role in the development of experimental techniques, platforms, and diagnostics that are eventually fielded on the National Ignition Facility. The facility fields in excess of 2300 experiments a year, supporting both ICF and fundamental HED research. Images of the Omega facility are shown in Fig. 4.

The Omega-60 laser is a Nd:glass laser producing approximately 978 J per beam at the fundamental (1ω) wavelength of 1053 nm (Boehly et al., 1997). The beams are frequency tripled to 3ω , or 351 nm, before being transported to the target chamber. Following frequency conversion to 3ω , the resulting energy per beam is approximately 750 J. Thus, the 60-beam system can deliver more than 40 kJ with peak powers up to 45 TW (Boehly et al., 1997). The facility is capable of producing arbitrary laser pulse shapes from 0.1 ns to 4 ns in length. Additionally, the lasers employ an array of different beam smoothing capabilities including spectral dispersion (SSD) in two dimensions, polarization smoothing, and random phase plates. Omega has the most advanced beam smoothing capabilities of any implosion system. Such smoothing techniques are critical for direct-drive approaches to ICF, as spatial and temporal smoothing of the laser energy deposition onto the target is essential for minimizing the seeding of hydrodynamic instability growth.

The Omega-60 system is specifically configured for laser-direct-drive studies with the beams being arranged symmetrically around the target chamber with a fivefold rotational symmetry about the vertical axis (Boehly et al., 1992). The target chamber is 3.3 m in diameter and has a total of 92 ports; 60 beam ports and an additional 32 ports for diagnostics (Boehly et al., 1992). As a result of the role that the Omega laser facility plays in the development of diagnostics for the NIF, the facility hosts some of the most advanced particle and radiation diagnostics in the world for characterizing ICF implosions and HED plasma. In addition to the advanced diagnostics, the facility also has a pulsed magnetic field generator called the magneto-inertial fusion electrical discharge system (MiFEDS), capable of generating 15 T fields for the study of magnetized inertial fusion and magnetized-HED plasma science (Fiksel et al., 2015).

Alongside the Omega-60 facility, the LLE also hosts the Omega Extended Performance (EP) system (Waxer et al., 2005). The OMEGA-EP system has four, frequency-tripled (3ω), kilojoule class, independently configurable beamlines, two of which can be

Fig. 4 (A) Image of the target area for the Omega-60 laser. (B) Image of the laser drivers for the Omega-60 laser. (C) Image of the Omega-EP beam lines. Image (A) <https://www.lle.rochester.edu/index.php/omega-laser-facility-2/omega-laser-system/omega-experimental-systems/>; (B) <https://www.lle.rochester.edu/index.php/omega-laser-facility-2/omega-laser-system/omega-laser-drivers-2/>; (C) <https://www.lle.rochester.edu/index.php/omega-laser-facility-2/6271-2/omega-ep-beamlines/>

compressed for short pulse, petawatt-class operation enabling a wide range of experimental configurations (Meyerhofer et al., 2010). The integration of Omega-EP with Omega-60 provides an expanded capability for enhanced radiography as well as the study of fast ignition concepts.

As of 2019, the two short-pulse capable beams can provide 1ω , 1053 nm, light with up to 0.5 kJ in 0.7 ps, 1.25 kJ in 10 ps, or 2.3 kJ in 100 ps. When operated together, the two short-pulse beams propagate to two perpendicular off-axis parabolas in the OMEGA-EP target chamber, or alternatively are combined to co-propagate along a single axis. In any short-pulse configuration, the two remaining beams can provide simultaneous long-pulse operation for target preconditioning. It is also possible to transport the short-pulse beam(s) to the OMEGA chamber for integrated operation with the OMEGA-60 laser. Alternatively, all four of the OMEGA-EP beams can provide long-pulse (0.1–10 ns) operation to the OMEGA-EP target chamber. Each long-pulse beam is frequency-tripled to 351 nm, having energy up to 5 kJ, and with the ability to individually configure each laser pulse shape. Over 80 qualified diagnostics are available for experiments at the OMEGA-EP chamber. Three dedicated Target Positioning Systems (TPS) enable control for multi-target geometries.

Iskra 5 (Sarov, Nizhny Novgorod, Russia)

The Iskra 5 laser is located at the Russian Federal Nuclear Center, All-Russian Scientific Research Institute of Experimental Physics (RFNC-VNIIEF) in Sarov, Nizhny Novgorod, Russia. Completed in 1989, Iskra 5 is a 12 beam, 30 kJ (100 TW) facility created to study indirect drive target physics as well as the behavior of hot and dense plasma (Kirillov et al., 1990).

The Iskra 5 laser is a flash-lamp pumped, photodissociative iodine laser, producing 2.5 kJ of energy per beam at the fundamental (1ω) wavelength of 1316 nm (Kirillov et al., 1990). The beams are arrayed around a target chamber measuring 2 m in diameter. In 2002 the Iskra 5 laser was modified with a conversion to the second harmonic at 657.6 nm, giving it the capability of operating at either 1ω (1316 nm) or 2ω (657.6 nm) wavelength (Annenkov et al., 2003). The energy in each beam at 2ω is 220 J in 5 ns, and thus, when operating at 2ω , the facility can deliver a total energy of 2.6 kJ in 5 ns to a target. The facility hosts an array of diagnostics for measuring X-ray radiation, studying flows of charged particles, neutron counters, and plasma temperature (Gus'kov et al., 2010; Kirillov et al., 2000; Abzaev et al., 1998).

Shen-Guang-II Upgrade (Shanghai, China)

The Shen-Guang II Upgrade (SG-II UP) is located at the National Laboratory on High Power Laser and Physics (NLHPLP) of the Shanghai Institute of Optics and Fine Mechanics (SIOM), Chinese Academy of Sciences (CAS), in Shanghai, China. The SG-II UP facility was designed specifically for studying ICF and, particularly, fast-ignition concepts, as well as other basic HED science. The SG-II Upgrade Facility began operation in 2016, delivering eight beams with a total energy of 40 kJ in 3 ns at 1053 nm and 24 kJ in 3 ns at 351 nm (Zhu et al., 2018). Images of the SG-II UP facility are shown in Fig. 5.

The SG-II UP nanosecond laser is a Nd:glass laser capable of delivering a maximum of 8.5 kJ in 5 ns per beam at the fundamental (1ω) wavelength of 1053 nm. The beams are transported to the final optics assembly located at the 2.6 m diameter target chamber, where the frequency is tripled to 3ω , 351 nm, before being focused to TCC using a wedged focus lens (Zhu et al., 2018). The SG-II U facility is configured for studying indirect-drive target concepts, with the beams being clustered near the polar regions of the top and

Fig. 5 (A) Image of the laser hall for Shen-Guang II UP laser. (B) Image of the Shen-Guang II UP target chamber. Image Zhu J et al. (2018) Status and development of high-power laser facilities at the NLHPLP. *High Power Laser Science and Engineering* 6: 1–23. doi: <https://doi.org/10.1017/hpl.2018.46>.

bottom hemispheres. Four beams are injected in each hemisphere, with the beams being equally distributed in the azimuthal direction and being situated on a single cone of polar angle 50 degrees (Tian et al., 2019).

The SG-II UP system supports a pulse shaping capability for delivering sophisticated ignition-relevant laser pulse shapes. The facility hosts a number of important ICF diagnostics, including hard X-ray imaging, X-ray spectrometers, and neutron time-of-flight (nTOF) (Zhu et al., 2018; Cui et al., 2021). Recently, the SG-II UP facility has added a pulsed magnetic field generator capable of producing an 8.8 T field using a double-turn, i.e., Helmholtz, coil (Hu et al., 2020), enabling studies of magneto-inertial fusion as well as magnetized HED plasmas.

Accompanying the SG-II UP nanosecond laser system is the SG-II UP PW picosecond laser system that delivers 1 kJ of energy in 1–10 ps at the fundamental (1ω) wavelength of 1053 nm (Zhu et al., 2018). SG-II UP PW employs a hybrid technology that combines optical parametric CPA (OPCPA) and Nd:glass CPA. This short-pulse, PW class laser system provides enhanced research capability to the facility as it expands the range of diagnostics that can be fielded, while also serving as an independent heating beam for fast ignition studies.

Gekko XII & LFEX (Osaka, Japan)

The Gekko XII facility is located at the Institute for Laser Engineering (ILE) at Osaka University, Osaka, Japan. The Gekko XII facility was completed and became operational in 1983 (Chiyo Yamanaka et al., 1981). The facility comprises 12 beams, capable of delivering approximately 10 kJ of total energy in 1.7 ns (Nakai et al., 1992), though, at present, routinely operates at approximately 4.5 kJ in 1.5 ns (Shiraga et al., 2011). Today, the Gekko XII facility houses two separate target chambers and maintains the capability to either symmetrically drive targets (Chamber 1) or illuminate a target from a single side (Chamber 2) at high power by combining the 12 beams into a single beam (Miyanaaga et al., 2000).

The Gekko XII laser is a Nd:glass laser producing 2.5 kJ per beam at the fundamental (1ω) wavelength of 1053 nm. The beams are frequency doubled (2ω) to 527 nm for routine operations, and are capable of delivering approximately 800 J per beam. The lasers are arranged with a dodecahedron orientation around target chamber 1. The facility maintains an array of plasma diagnostics for diagnosing implosions such as X-ray streak cameras, X-ray framing cameras, neutron spectrometers, and electron spectrometers.

Within the Gekko XII facility, the Laser for Fast Ignition Experiment (LFEX) (Miyanaaga and Kawanaka, 2011) has been developed and deployed as an auxiliary heating beam for fast-ignition studies as part of the Fast Ignition Realization Experiment (FIREX) project (Azechi, 2016). The LFEX laser is a four beam, Nd:glass laser based on CPA technology and capable of delivering up to 700 J in 1 ps per beam, or 2.8 kJ in 1 ps total, at the fundamental (1ω) wavelength of 1053 nm (Shiraga et al., 2015). In 2015, The LFEX laser achieved the record for being the world's most powerful laser when it output 2 PW of power. The record was recently broken in 2019 by the ELI-NP (Extreme Light Infrastructure—Nuclear Physics) laser that output 10 PW of power [https://optics.org/news/10/3/41].

Pulsed Power Facilities

Alongside laser facilities, pulsed-power instruments are the only other class of major ICF facility capable of imploding targets with fusion fuel. The term pulsed-power is a general reference to the use of high-power, high-current systems that utilize the Lorentz force to “magnetically” compress material. The technology used to create the drive current varies, ranging from conventional electric power storage in capacitor banks to the use of high-explosives. Here, the major pulsed-power drivers for ICF are reviewed and listed in Table 2.

Z-Facility (Albuquerque, NM, United States)

The Z-facility is located at Sandia National Laboratories in Albuquerque, NM, United States. In 2007, the Z-facility completed a refurbishment that delivered improved precision and laser pulse shape variability, increased the shot capacity, and increased the delivery current (Weinbrecht et al., 2007). In addition to ICF research, the Z-facility is a significant capability for a wide range of HED science, including radiation source development, radiation-driven science, and dynamic material properties (Sinars et al., 2020). Images of the Z-facility are shown in Fig. 6.

Table 2 List of major pulsed-power ICF facilities worldwide.

Facility	Location	Systems/type	Key parameters (Current/time)	Status
Z-facility	United States	Z-pinch/Marx	30 MA/100 ns	Operational
		Z-Beamlet/Nd:glass	0.6 kJ/0.2 ns/527 nm	Operational
Julong-I (PTS)	China	Z-pinch/Marx	10 MA/90 ns	Operational
Angara-5-1	Russia	Z-pinch/Marx	5 MA/100 ns	Operational

Fig. 6 (A) Z-Facility. Photo by Randy Montoya (B) Center load section of the Z-facility. Image <https://www.energy.gov/nnsa/articles/meet-machine-z-machine-creates-conditions-found-nowhere-else-earth>

The Z-facility can store up to 22 MJ in a ring of Marx generator capacitor banks around the perimeter of the machine, each of which is capable of storing 632 kJ. This energy can be discharged in 100 ns, and can deliver a peak current of up to 30 MA and peak power of 80 TW. This translates to the ability to deliver approximately 3 MJ of energy to a target and the surrounding load hardware (Sinars et al., 2020). The Z-facility maintains a wide array of X-ray and optical diagnostics, both spectroscopic and radiographic, for characterizing material behavior and properties.

While the Z-facility was optimized to drive the Z-pinch dynamic hohlraum for magnetic-indirect-drive ICF concept studies (Matzen et al., 2005), the leading ICF concept being developed on the Z-facility today is called Magnetized Liner Inertial Fusion (MagLIF) (Slutz and Vesey, 2012). Rather than the implosion of a wire-array target, as in the case of a dynamic hohlraum, the MagLIF concept entails the implosion of a solid metal “liner,” in conjunction with “pre-heating” of the fusion fuel by the Z-beamlet laser, described below, and the application of a background magnetic field to reduce thermal conduction losses from the fusion fuel thereby relaxing the compression requirement for achieving ignition.

In addition to the Z-pinch, the Z-facility also hosts the Z-beamlet laser (Rambo et al., 2005). The Z-beamlet laser is based largely on the Beamlet laser built by Lawrence Livermore National Laboratory as the prototype “unit laser cell” for the National Ignition Facility. Upon decommissioning of the Beamlet laser in 1998, it was moved to SNL for integration with the Z-facility. The Z-beamlet laser is a Nd:glass laser that delivers 0.6–2 kJ of energy in 0.2–2 ns at 527 nm (2ω). The Z-beamlet laser provides a powerful tool for both radiographing implosions on the Z-pinch, and heating the central fuel in MagLIF targets.

Julong-I, Primary Test Stand (Mianyang, China)

The Julong-I, Primary Test Stand (PTS) facility began operations in the 2012–13 time frame, and is located at the Key Laboratory of Pulsed Power, Institute of Fluid Physics, China Academy of Engineering Physics (CAEP), in Mianyang, China. The PTS is a multi-terawatt facility capable of delivering 8–10 MA of current with rise-time of approximately 90 ns (Deng et al., 2013, 2015, 2016). The system comprises 24 modules that include, among other things, a Marx generator, an immediate storage capacitor, as well as a laser-triggered spark-gap switch. The facility hosts a variety of X-ray and optical diagnostics for characterizing pinch plasmas as well as material behavior and properties (Deng et al., 2016). Images of PTS facility are shown in Fig. 7.

Angara-5-1 (Moscow, Russia)

The Angara-5-1 facility is located at the Kurchatov Institute, National Research Center, Moscow, Russia. The facility has been in operation since 1984 (Al’bikov et al., 1990). The Angara-5-1 is a Z-pinch facility capable of delivering 5 MA with a rise time of 100 ns (Aleksandrov et al., 2008). The facility comprises eight modules, placed radially, occupying an area 50 m in diameter. In the center is a concrete, radiation-shielding ring 10 m in diameter (Al’bikov et al., 1990). The facility has a maximum storage capacity of 650 kJ, and power of 9 TW (Al’bikov et al., 1990).

The Angara-5-1 facility routinely fields experiments using wire-array (Mitrofanov et al., 2020) targets for ICF studies, but also facilitates a wide range of HED (Grabovski et al., 2016) and materials (Aleksandrov et al., 2019) research. As such, the facility maintains a wide array of both X-ray and optical diagnostics, as well as magnetic probes, for characterizing pinch plasmas as well as material behavior and properties.

(2016) From concept to reality—A review to the primary test stand and its preliminary application in high energy density physics. *Matter and Radiation at Extremes* 1(1), pp. 48–58. doi: <https://doi.org/10.1016/j.mre.2016.01.004>.

Other ICF relevant physics facilities

In addition to the major ICF implosion instruments described in the preceding sections of this article, key physics R&D supporting the advancement of ICF science is executed on a wide array of smaller facilities. These facilities, while not considered major facilities for the purposes of this article, are providing essential data for the advancement of ICF and IFE. This includes facilities such as ORION (Hopps et al., 2015), LULI 2000 (Zou et al., 2008), and NIKE (Obenschain et al., 2015).

At this time, there are no major integrated facilities for prominent alternative approaches to IFE such as heavy-ion fusion. Nevertheless, research continues on facilities such as the Neutralized-Drift-Compression-Experiment II (NDCX-II) (Waldron et al., 2009), and will be featured at future facilities such as the Facility for Antiproton and Ion Research (FAIR) in Germany (Rosner, 2007), and the Heavy Ion Research Facility at Lanzhou (HIRFL) China (Zhan et al., 2008).

Lastly, the emergence of coherent X-ray light sources, such as the European XFEL [<https://www.xfel.eu>], LCLS [<https://lcls.slac.stanford.edu>], and SACLA [<http://xfel.riken.jp/eng>], coupled with high-energy and high-intensity optical laser systems, stands to provide unique and essential capabilities for unraveling, at a fundamental level, the complex interactions that occur in the environments in which energy couples to the capsule and is transferred to the fusion fuel in ICF targets.

Acknowledgments

The author would like to thank Dr. John Kline for fruitful discussion and editing as well as Dr. E. Michael Campbell and Dr. Daniel Sinars for comments and feedback on the material.

The enduring commitment to nuclear fusion research has been motivated in large part by its potential to deliver large scale commercial energy production. Achieving this will require a deep understanding of the difference between achieving meaningful fusion gain in the laboratory and delivering commercially viable power plants. Issues of technology, economics, safety and public acceptance can make or break an energy source, even one with a sound scientific basis.

The purpose of the chapter is to discuss the requirements for commercial fusion energy systems and to describe some of the design tradeoffs involved. Because this is a chapter on IFE power plants, the focus is on pulsed systems operating above the threshold to achieve fusion ignition and gain (i.e., when there is a propagating burn wave that yields net energy output). However, much of the material is sufficiently general to apply to both IFE and MFE systems.

This article is divided into four sections:

- (1) A brief introduction of the basic principles and design considerations for an economic plant;
- (2) A summary of “end user” requirements that need to inform the design of power-producing plants and any intermediate prototype steps;
- (3) Explanation of how the different technology elements of the system interact with each other to impact the overall design and viability of the plant;
- (4) Example design studies and parameters for integrated IFE power plants.

Introduction

Plant electrical gain and minimum fusion gain

All power plants require electrical energy to run the various plant systems to extract energy from the fuel and deliver electricity to the marketplace. In most types of power plants, this energy is relatively low, a few percent of the output of the plant. But in fusion power plant designs the electricity required to run the plant is typically much larger, perhaps 20–30% of plant output, and is called the recirculating power, as illustrated in Fig. 1.

The reason that the recirculating power in a fusion plant is so high is that fusion is a threshold process. Typically, a large amount of energy is expended to heat and compress the fuel to achieve the conditions for fusion, and only after the ignition threshold is

*Visiting Scientist.

Fig. 1 Basic flow diagram for an IFE power plant, highlighting the fact that fusion power requires a non-trivial amount of electricity to generate electricity.

reached is there meaningful energy gain. Oftentimes, once threshold has been reached, the marginal cost of producing additional gain is low. As a result, the largest operating cost in the plant can be the cost of providing the driver energy needed to achieve threshold.

The relatively high recirculating power in fusion systems leads to a fundamental requirement concerning the total amount of power generated by the plant and that delivered to the grid. **Fig. 2** shows a basic calculation of relative plant cost as a function of plant electrical gain, for a plant with fixed electrical output to the grid. At gains less than about 3, the plant cost rises sharply. The reason is that as plant electrical gain becomes smaller, more and more of the plant electrical generation is being used to offset the power needed to run the fusion driver. In the extreme case of a plant electrical gain of zero (i.e., net breakeven), all the plant's output is being recirculated to operate the driver and nothing is sent to grid. Commercially viability is a complex topic, but as a general guide a fusion plant must have a net electrical gain greater than about 3. When one considers the likely electrical efficiency of the fusion driver and the systems that convert fusion energy to electrical energy, this leads to a requirement for minimum commercially viable fusion gain.

Fig. 2 Relative thermal plant cost (excluding driver cost) versus net plant electrical gain, G_p , which is defined as the ratio of the energy supplied to the grid to the energy needed to run the plant, $G_p = P_{\text{grid}}/P_{\text{recirc}}$.

The required gain from the fusion system (G_F) can be expressed in terms of the driver efficiency (η_D), the electrical conversion efficiency (η_E), blanket gain (G_B) and the net plant electrical gain (G_P). As an illustrative example, if we set the electrical conversion efficiency to 0.4, typical of steam turbine systems, the driver efficiency to 0.1, representative of laser drivers, blanket gain multiplication from exothermic reactions (M) of 1.1, then the required fusion gain required to close the loop is about 100. The required fusion gain, G_F , in this context means the ratio of the useful fusion output power to the incident driver power (noting that the useful output needs to account for any losses due to incomplete geometrical coverage by the blanket—for example due to driver penetrations—and whether the power associated with ion and X-ray output is able to be transferred efficiently to the heat exchange system).

$$G_F = \frac{(G_P + 1)}{M \cdot \eta_D \cdot \eta_E} \quad (1)$$

Eq. (1) provides required fusion system gain in terms of net plant electrical gain and major system efficiencies. The reasoning that underlies this conclusion is simple, but the conclusion is of profound importance to fusion power plant designers. In essence, the first question that the developer of a candidate fusion system should ask is whether there is a plausible case for achieving the minimum required fusion gain. This is a necessary, although not sufficient requirement for commercial viability. One consequence of this requirement is that, for pure fusion systems,¹ ignition and self-propagating burn is required in order to achieve adequate fusion gain for commercial purposes. In turn, this highlights a second important parameter, the threshold energy for fusion ignition, which will be considered in the next section.

Note that increasing the fusion gain offers the best chance of increasing plant gain, since (1) for a given driver type there is limited ability to increase driver efficiency, (2) the thermal conversion efficiency is limited by practical limits on coolant temperature, and (3) for pure fusion the blanket gain is limited to about 1.1–1.2. In contrast, fusion gain can be increased significantly by increasing the driver energy, but this comes at the cost of a more expensive driver. As a result, we typically find a minimum in the total cost of the power plant (thermal plant, driver and target factory) and cost of electricity as a function of driver energy (and corresponding plant gain) for fixed net electric output

Threshold energy, minimum plant size, minimum single shot fusion yield.

The threshold energy for commercially meaningful fusion gain is one of the most important parameters affecting fusion power plant design. Threshold energy, which is a function of the physics solution adopted in the target design, determines the minimum size for the fusion driver. Below-threshold drive energy produces no revenue. A large threshold energy requires a large fusion driver (with its up-front capital cost), which then requires a larger power plant in order to generate the revenue needed to pay for it. As a result, threshold energy is one of the primary determinants of minimum viable plant size and is the reason why many fusion power plant designs optimize at large plant sizes.

Less obvious is that, for IFE plants, threshold energy is a primary determinant of the minimum “single-shot” fusion yield. Recall that economic considerations require a minimum plant electrical gain, which in turn requires a minimum fusion system gain. Achieving the minimum required fusion gain requires going above the fusion threshold energy. Because single shot fusion yield is the product of driver energy and fusion gain, the threshold energy sets a lower limit to the fusion yield.

If the minimum single shot yield is high, it complicates the fusion chamber design. For example, consider a 1 GWe fusion power plant that has a 1 GJ (10^9 J) single shot fusion yield. One GJ is the energy equivalent of 220 kg of TNT, albeit with lower blast due to the small mass of the target. To generate 1 GWe would require 65 million such fusion events each year. The challenges to power plant mechanical and thermal designs are readily apparent. Plant designs with such high single shot yields often rely on the development of technologies such as flowing liquid metal curtains, in an attempt to deal with the thermal, mechanical and radiation consequences.

If the single shot yield is low, the target injection rate needs to go up in order to produce the sustained output required for a power plant. This makes the already difficult problem of target manufacture, injection, tracking, ignition and waste disposal even harder and perhaps out of reach. However, once threshold energy has been reached, single shot fusion yield can be increased by increasing driver energy, providing a path to an acceptably high single shot yield, if all the other terms can be made self-consistent.

It's worth noting that the conclusions just discussed are derived solely from economic and simple energy balance considerations:

- Economics require that the net plant electrical gain be in the range of three or greater so that the costs of operating the fusion driver are not overwhelming.
- Once values for driver and electrical conversion efficiencies are determined, one can specify a minimum fusion gain required to achieve the desired plant gain.
- Achieving minimum fusion gain requires operating above the fusion ignition threshold energy for the driver.
- Threshold energy is a primary factor in determining minimum economically viable plant size; high threshold energy requires large plant size to pay the cost of achieving ignition.

¹Fission-fusion hybrid systems can in principle achieve sufficient gain without ignition.

- Threshold energy, combined with minimum fusion gain, determines the lower limit to single shot fusion yield. Single shot fusion yield is a primary driver for the design of the fusion chamber.
- Finally, single shot fusion yield, combined with power plant output power, sets the requirement for target injection rate.

In summary, quite a lot can be learned about the commercial viability of different fusion energy schemes from just these simple considerations. We turn now to other considerations that drive the power plant design, and then assess how these requirements impact the choice and integration of different paths to fusion. At the end of the chapter, an overview is provided of different IFE plant concepts that have sought to address these challenges.

IFE power plant design considerations

End-user requirements from utilities and suppliers

For any complex system, it is essential to guide the development path with a clear set of end-user requirements, even if many aspects may not be able to be met in intermediate demonstration facilities. This is in order to maintain a robust understanding of how different options for technology choices or system configurations could affect the ability to progress to the end product, and thus to avoid dead-end research directions. In the case of fusion, these requirements largely derive from the long-term needs of the electric utility companies (or process heat users), along with the power plant vendors (and associated supply chain) and primary stakeholders such as the public and the regulatory agencies.

An illustrative starting point is the Utility Requirements Document for Advanced Light Water Reactors (EPRI, 1999). The comprehensive nature of this type of approach can be coupled with industrial perspectives of fusion power delivery requirements (Vondrasek, 1982; Kaslow et al., 1994; Dean, 1999; Kadak et al., 2012), analyses of the anticipated safety licensing requirements for fusion power delivery, and the commercial impact of different technology options for a power plant (Anklam et al., 2011; Goto et al., 2006).

Working from these criteria allows the power plant design process to focus on operational characteristics that are familiar to the end-users (utilities), delivery industries (vendors) and regulators. It allows trade-off decisions to be made on the wide array of possible development and risk-reduction activities, and enables down-selection of options consistent with the final goal of robust, economically competitive electricity production.

Criteria that drive the design process for an IFE power plant should include the following:

- i. Ability to supply baseload power:
 - This typically translates into > 100 MWe scale output with high availability ($> 85\%$ service factor), and the need for predictable shutdown and rapid restart (the importance of which scales with the power capacity of the plant). Ideally the power would be dispatchable (i.e., able to respond promptly to varying demand), if financially acceptable.
- ii. Ability to meet the highest levels of urban environmental and safety standards:
 - Economics and logistics preferentially drive the co-location of power plants with load centers such as cities, while public acceptability requires that there be minimal need for off-site emergency planning, and an operator safety level comparable to existing technologies. An acceptably small footprint for such a site requires detailed consideration of the consequences of hazards such as fire (which can disperse radioactive materials), a breach of the shield wall (which can lead to exposure to prompt radiation from activated materials in the reactor volume), and permeation of tritium into the local environment. In turn, these drive a wide range of system choices, detailed below, with examples such as chamber designs that minimize residual decay heat in the event of system shutdown, and target and chamber designs that permit small and segregated tritium inventories.
- iii. Licensing predictability and global deployability:
 - This is a complex and evolving area, and is perhaps the principal non-technical hurdle that could inhibit deployment if not addressed in a timely manner, as has been seen for many advanced nuclear fission schemes. Licensing considerations directly drive the plant design in areas such as radioactive materials inventory (from tritium, activated target and chamber materials, and byproducts in the cooling loops), as well as the blanket design (e.g., choice of coolant) and shield wall construction.
- iv. Capital build—duration, cost (\$) and intensity (\$/W), with acceptable return on equity (ROE):
 - The up-front (capital) cost for a fusion plant can present a major barrier to entry, particularly for commercial markets such as the US where the market capitalization of the utility companies militates against financing a multi-\$B construction project. The necessary presence of specialized equipment (e.g., lasers) and uncertain duration for licensing approvals impose constraints on the plant design that translate into physics parameters such as the need for high fusion gain (to minimize driver cost), and avoidance of novel nuclear-grade structural materials (that could challenge timely regulatory approval).
- v. Levelized cost of electricity, LCOE (\$/kWh):
 - Price-sensitive markets such as electricity generation drive fusion to large-scale systems (nominally > 0.5 GWe, with the upper bound set by an acceptable impact grid stability, which is typically < 2 GWe). This can be in direct conflict to the difficulties of financing such large plants (as noted above). System models point to the impact of the choice of structural materials (which drives the overall plant performance and maintenance regime); the cost of manufacturing

targets; the importance of high gain; and a surprising insensitivity to some parameters such as driver efficiency under certain conditions.

vi. Low environmental impact:

- A primary attraction of fusion, compared to conventional fission, is the prospect of a manageable waste stream of nuclear byproducts during operation and at decommissioning. This outcome is far from assured, requiring targeted development of low-activation structural materials, mitigation of first wall bombardment (that can lead to highly radioactive “dust”), and (for IFE) suitable choice of target materials.
- As a thermal energy plant (for conventional DT reactions), the use of water for cooling towers and the impact of local heating on the associated river/ocean, is an environmental consequence that can be mitigated by driving to higher temperature operations (and possibly direct electrical conversion in the long term).

vii. Protection of capital assets against operational risk and innovation:

- Often overlooked, this term can impact whether the overall approach to fusion would be acceptable to a commercial market. Failure modes need to be such that they do not hold the entire plant at risk of write-off or prolonged downtime. For example, the probability of an event that compromises the operability or structural integrity of the reactor vessel needs to be vanishingly small.
- Conversely, given the pace of progress in the high technology areas such as lasers, the owner/operator needs to be confident that they could upgrade their systems in the event of a disruptive advance in efficiency or cost (e.g., the ability to adapt to improved target designs).

viii. Robust supply chain, including fuel supply, technology availability, and materials scalability:

- The plant should be constructed from materials that have sufficient availability so as to not constrain the rate of rollout of a fleet, or overly limit its geographical extent.
- Where possible, the plant equipment should be transportable using conventional modes of shipping over public highways, including during decommissioning and waste disposal.

ix. Widespread availability of operations staffing:

- Widespread deployment requires a plant design consistent with an operations and maintenance (O&M) regime that can make use of a relatively conventional power plant workforce, with minimal requirement for scarce expertise (e.g., plasma physicists).

While a number of these criteria (e.g., cost of electricity) are difficult to predict in an absolute sense with high accuracy, the relative benefit of different design choices can still be assessed. For example, from a financial point of view, an option in which additional capital investment leads to a reduced cost of electricity can be assessed by comparing the operational savings with the cost of amortization of the increased capital.

Other criteria (e.g., availability and maintainability) drive fundamental design choices in the overall power plant architecture, sub-system configurations, and acceptability of certain technology. For example, as will be shown below, the impact of designing a laser sub-system that can be maintained while the plant remains operational is of over-riding importance. This allows the power plant availability to remain high even if the reliability or longevity of a critical sub-system is relatively low.

Overall, it is instructive to compare the anticipated market positioning of fusion with that of other current and emerging low-Carbon energy technologies, particularly for the primary use-case of baseload electricity provision (MacKay, 2008). Fusion has many inherent advantages due to the quasi-continuous nature of the power generation that is consistent with baseload supply to existing grids. It also offers the potential for security of supply if the plant design avoids the need for geographically restricted materials (such as rare earths), in addition to the avoidance of enrichment and reprocessing cycles that may be needed for fission.

Attributes of IFE to address the end-user requirements

The above “end-user” requirements can be translated into a set of attributes to drive technical design choices for an IFE power plant, at both a qualitative and quantitative level—with the latter needing system-level optimization models to assess aspects such as performance, cost, availability, and risk.

While the primary near-term focus of the fusion community is necessarily on achieving the desired thermonuclear performance, prime importance needs also to be on ensuring that the physics solution can ultimately be made consistent with a path to the required plant availability, maintainability and reliability, costs of electricity and construction, protection of capital investment, licensing simplicity, safe operations, and timeliness of rollout.

To this end, the following attributes can be adopted to inform any given plant design.

Compatibility of the integrated performance cycle with power production at scale

At its most simplistic level, there needs to be a self-consistent set of parameters for the major elements of the system, including:

- Driver² output and efficiency (from wall-plug to energy on target, accounting for all ancillary systems, beam transport losses, and sustained operating parameters).

²Throughout this chapter, the term “driver” is used as shorthand for the chosen pulsed device, whether Z-pinch, particle beam or optical laser.

- System repetition rate (which is likely limited by the reset time of the interaction chamber).
- Fusion target gain (energy output/driver energy incident), in which the output energy is only that fraction which is available to heat the thermal blanket.
- Blanket performance (accounting for the absorbed fraction of incident neutrons, and any inelastic reactions that can amplify the power), and in particular the need for tritium breeding at a rate to assure self-sufficiency.
- Thermal power cycle efficiency (accounting for any intermediate loops that may be needed for safety isolation of the primary circuit).
- Power needed for auxiliary systems ("house power"), mitigated by any energy capture from the low-enthalpy rejected heat.

An example power performance cycle is presented in Fig. 3.

Meeting the RAMI³ requirements for baseload power

It is inevitable that in a system as technologically complex as fusion, there will be failures or degradation of individual components throughout the life of the plant, and the need for periodic maintenance to ensure suitable longevity. It is likely that the mean time between failure (MTBF) for high technology components could be relatively short, particularly in the early phases of plant deployment. It is imperative that such events do not hold the power production at risk at a level that substantially impacts the overall plant availability, or in a manner that can lead to unpredictable reductions in power output that could compromise the stability of the electrical grid. Plant intermittency resulting from failure of individual components in any fusion system would likely be deemed unacceptable for a baseload source of energy.

The need to avoid relying on the integrated operation of a highly complex and coupled system should be a primary driver for any plant design. One primary mitigating approach is to configure the plant as a set of modular, parallelized Line Replaceable Units (LRUs) at a scale that allows single units to fail (or be taken out of service for maintenance) while allowing the rest of the plant to continue to function. Where possible, this approach should be used to decouple the *reliability* of high-threat, limited life components (such as final optics) from impacting the overall plant *availability*.

The quantitative requirements for each sub-system (e.g., laser box) will depend on their MTBF and mean time to repair (MTTR), along with any headroom designed into the sub-systems to compensate for non-working neighbors. See Fig. 4 for an example from the LIFE plant design (Dunne et al., 2011) that shows how power plant availability can be largely decoupled from sub-system reliability (Bayramian et al., 2011).

For IFE, this modular approach can help enable a separable development program in which the performance of individual sub-systems can be locally optimized. In the longer-term, it also allows for the creation of a cost-effective supply chain via off-site factory manufacture and truck-based delivery of the specialized equipment.

Availability of key materials

A primary materials problem is the first wall of the fusion chamber, which has to withstand intense and sustained bombardment of neutrons, X-rays and ionic debris from the exploding targets. The pace of fusion delivery could be driven in part by the long time-scales associated with advanced materials development and certification for high-threat components (e.g., low-activation, long-lifetime structural materials). Such advanced materials are still highly beneficial, but intermediate solutions would permit more timely deployment of an initial fleet. Some chamber designs may permit liquid walls, or wetted walls (if a self-consistent solution

Fig. 3 Illustrative power cycle for a laser-driven IFE plant.

³RAMI stands for reliability, availability, maintainability, inspectability.

Fig. 4 Illustrative example of the impact of having a line replaceable unit “laser box” on power plant availability. The graph shows the result of a Monte Carlo simulation of plant operations as a function of beam-box mean time between failure (MTBF) and mean time to replace (MTTR). Plant availability is impacted by less than 1% even at very conservative failure rates for this design that incorporates a sufficient number of parallel line-replaceable units (384 laser boxes) and 15% headroom in total laser power.

can be found with the other sub-systems, as discussed below), but where this isn’t possible then means must be found to treat the first wall and blanket as Line Replaceable Units themselves, consistent with a few-year (rather than few-decade) lifetime.

Another key materials problem is the need for a non-trivial inventory of tritium for start-up and initial operations, with some fusion power plant designs requiring levels comparable to the total available global inventory. This presents a substantial obstacle to fusion power plant delivery. By virtue of the high fractional burn-up of fuel within an IFE capsule, then through suitable choice of target manufacturing approach, and selection of a high-solubility coolant in the blanket, the tritium inventory may be able to be reduced by an order of magnitude or more, to less than 1 kg per plant (Reyes et al., 2017).

As an example of a broader materials consideration, the design of the specialized systems (such as lasers and targets) should be compatible with low cost, mass markets production using materials that can be sourced around the world. Sub-systems tradeoffs between alternate designs should not just assess raw performance, but should account for the ability to scale-up and be deployed on a global scale at an acceptable cost and risk.

A primary example is the target design, for which exotic materials and manufacturing processes are acceptable for the “single-shot” proof of performance, but which may need substantial changes (and likely compromises in performance) in order to achieve high volume, low-cost targets that are also compatible with injection into the harsh environment of a cycled IFE chamber, and subsequent extraction and recycling of the inert target materials.

Criteria for intermediate demonstration systems

It is likely that one or more intermediate facilities will be needed to drive progress from an initial demonstration of physics performance (likely in a “single shot” mode within a highly instrumented and optimized science facility), to a prototype that can demonstrate integrated system performance in a power-plant-compatible mode (e.g., performance at a suitable repetition rate), to a demonstration plant that delivers net power output (likely in a non-commercial mode initially).

The integrated plant design and its associated technology program should explicitly define the required performance levels at each stage, and understand the nominal path of progression from one step to the next and ultimately to a commercial plant. Without this guiding principle, it is likely that dead-end solutions will be adopted whose removal may impose unacceptable design changes, costs and delay.

Example requirements that should be met *prior* to the design and construction of a demonstration power plant (in order to reduce risk to acceptable levels) are a function of the risk appetite of the investors, but could include the following, which includes the use of Technology Readiness Levels, TRL (NASA, 2007) as a quantitative metric of maturity:

- Demonstration of “single shot” physics performance at the required level (or within an acceptable margin based on high-assurance modeling).
- Advanced prototypes (TRL 6) for non-nuclear sub-systems (e.g., fusion driver module, target injector, target tracking/engagement).
- Validation in laboratory or relevant environments (TRL 4 or 5) for elements that have to exist in the locality of the chamber (e.g., final optics, structural materials, tritium recovery).
- Production path for consumables (e.g., fuel targets, short-life optics).

- Quantitative operating model for the fusion chamber, including non-radioactive demonstrations of important operations such as first wall replacement.
- Agreed upgrade paths for rapidly evolving sub-systems (e.g., driver efficiency, target performance).
- Indicative regulatory framework for plant operations.
- Nominal compatibility of sub-system requirements and anticipated performance.

Subsequently, an example set of requirements for a pre-commercial demonstration plant could include the following, with an overall objective to demonstrate integrated performance at a level needed to attract vendors and utilities for subsequent deployment:

- Achieve full system operation (fusion output, blanket operation, closed tritium cycle, waste management, consistent with coupling to a thermal balance of plant).
- Demonstrate a path to acceptable sub-system efficiencies, consistent with progression to overall power delivery to the grid.
- Sub-system demonstration in the required environment (TRL 7 or 8) for elements that need a working reactor (e.g., first wall, blanket, tritium recovery).
- Full operational demonstration (TRL 9) for non-nuclear subsystems.
- Quantify reliability and maintainability of components, consistent with projection to an operating power plant.
- Demonstrate ability for safe and environmentally sustainable operations (e.g., no impact outside of the plant; worker safety; operational model; waste stream).
- Test accident scenarios to level required by the regulator.
- Test inspection and certification methodology for the regulator.
- Determine anticipated rate and cost of build, and M&O costs.
- Identify material and sub-system supply chain for roll-out.
- Demonstrate a path to acceptable grid compatibility (e.g., start up, shut down, availability), and/or high-temperature applications compatibility (e.g., for chemical processing).
- Demonstrate path to an acceptable cost of electricity, capital build cost, revenue stream, and return on investment.
- Demonstrate path to low-cost manufacturing of targets at scale of tens to hundreds of millions per plant-year.
- Full design model for roll-out plan.

IFE power plant systems integration and interrelationships between the primary technology areas

The integration of individual technology components required for an IFE power plant can be depicted as a functional diagram, as in Fig. 5. This shows the main process flow via interconnected boxes, along with process support functions and the governing regulatory framework. Boxes shaded blue represent systems and processes at a level of maturity that substantively meet the needs of an IFE power plant today. Boxes shaded orange represent IFE-specific technologies, but which are largely within the bounds of the immediate fusion community to address. Boxes shaded yellow represent areas with technical and programmatic risk that largely rely on external factors to determine solutions and ensure progress.

In many ways, development of these sub-systems can proceed in a relatively independent manner (e.g., improvements in driver efficiency, or performance testing of fusion capsules), and this is a primary hallmark of IFE that has allowed substantial progress without the need to build power-plant-like facilities as is the case for magnetic fusion energy, MFE. But there are some key interdependencies imposed by the integration requirements of an IFE reactor. Examples are highlighted below, for which any plant design needs to ensure self-consistency, as well as an equitable distribution of tolerances (for efficiency, availability, cost, performance, etc.). These interdependencies include:

Driver (e.g., laser, ion beam, Z-pinch)

- *Performance* consistent with the target design: (i) at the single-shot level, (ii) at the required repetition rate, and (iii) with acceptable degradation over time. This typically translates to the need for 10–30% headroom in single-shot performance at the start of plant operations, given the reduction in damage threshold for optical components subjected to repeated operation. 10 Hz operation corresponds to a billion pulses every 3 years.
- *Wall-plug efficiency* consistent with the target gain and overall plant performance requirements. This dependency is non-trivial and highly system dependent. It is not linear since if driver efficiency is reduced but remains reasonably high (~10%), the plant electrical output just needs to be increased slightly to provide the additional power to run the driver.
- *Reliability* consistent with required plant availability. Even for a robust driver, the high capacity factor and predictability demanded for baseload power translate to the need for periodic maintenance *during* full plant operations, including “hot swap” replacement of limited lifetime components such as final optics. For multi-beam technologies like lasers, this requirement can conceivably be met by installing an excess number of beamlines, such that a fraction can be offline at any given time. For integrated technologies such as a Z-pinch, it drives the need for high reliability across the full system, with sufficiently high mean-time-between-failure and rapid replacement when needed.
- *Robustness* and *accessibility* consistent with the fusion environment. The requirement for any final optics to survive direct view of the fusion target in a sustained manner is a primary challenge for laser IFE. Degradation over time is common in most designs

Fig. 5 IFE power plant functional diagram.

(with replacement cycles measured in weeks or months). But access to the final optics area is hindered by the extreme radiation environment during operations, the need for near full solid angle coverage by the chamber blanket system, and tight angular and position tolerances and delicacy of the optical components themselves. Three further constraints on the final optic system are that it needs to decouple the driver from the chamber vacuum; it needs to ensure tritium does not permeate into the laser system; and the placement of optics must be consistent with any chamber maintenance activities. For example, this could indicate a desirability for small transmissive optics confined to the polar regions, rather than large grazing incidence optics surrounding

the entire chamber. Similarly for pulsed power designs, there needs to be sufficiently low activation to enable robotic clean-up and replacement activities between shots and for periodic maintenance.

- *Beam pointing and focusing* needs to be resistant to the threat spectrum from the fusion reaction. One example is the formation of color centers in transmissive Fresnel optics from neutron bombardment that leads to laser energy loss and heating of the lens (Marshall et al., 1997; Latkowski et al., 2003). Another is the sensitivity of the wavefront to target debris on grazing incidence reflective optics, along with the difficulty in pointing and replacing such large components and the response of thin film coatings to neutron and gamma irradiation.
- *Beam propagation* consistent with the post-fusion chamber environment. The interaction of laser or particle beams with residual gas in the chamber and any deposits on the final optics needs to be benign, enabling suitably high transmission and beam quality on target. This is non-trivial given the sensitivity and tight tolerances of short-pulse beams propagating through fusion chambers whose scale size (hundreds of m^3) means that a timely return to pristine vacuum conditions is very challenging. This is further complicated by the complex byproducts from the target explosions and their inhomogeneous distribution around the chamber volume. In particular, chamber designs that call for the sustained presence of a residual gas to protect the walls from X-rays and ions, or that make use of liquid blankets or wetted walls, need to demonstrate consistency with the demands placed on beam propagation (as well as consistency with the injection of cryogenic fuel pellets, as discussed below).

Fusion fuel target

The primary focus of inertial fusion research has been on developing a target design that can demonstrate the required performance on a single shot basis. For an IFE power plant, this needs to be extended to incorporate the following:

- *Primary output*—The useful fusion gain and yield obviously need to be consistent with the requirements of the power plant cycle, and ultimately with an acceptable cost of electricity. The former translates to the focus on DT, not only because of its relative high reactivity, but also because of its high inherent gain (17.6 MeV fusion output from thermal ions at ~ 10 keV). In contrast, some “advanced” fuels do not have an adequate inherent gain for integrated plant operations. As an example, $p(^{11}\text{B},\alpha)2\alpha$ has an optimized once-through energy amplification factor of just ~ 12.9 , which is the ratio of the fusion output energy (8.7 MeV) to the energy of the incident particles (0.675 MeV at the peak of the fusion cross-section resonance). This low ratio is grossly incompatible with the requirement for overall power plant gain to be ≥ 3 once all the system inefficiencies are accounted for.
- *Acceptable byproducts*—The secondary output (X-rays, ions, chemical and particulate debris) needs to be consistent with the design of the wider system—typically the chamber first wall and final optics, but also the in-chamber chemistry and the waste processing system. This translates into a tight set of constraints on materials that can be used in the target. The high energy particle output needs to be tailored to be consistent with first wall survival; the target mass needs to be such that high momentum debris is not generated from unevaporated segments; the choice of elements needs to prevent the activation of long-lived isotopes; and the chemical byproducts need to be benign. As an example of the latter point, gold or uranium cannot be used since they would condense in the chamber and plate the inner walls (but these are currently the materials of choice for ICF hohlraums; alternatives such as Pb with a lower melting point would be needed). Similarly, carbon (an ablator of choice for many pellet designs due to its compatibility with manufacturing methods) can be highly problematic due to its ability to condense on the chamber walls and optics, form carbides that could embrittle the wall, and generate problematic compounds for the exhaust/waste systems, unless actively managed (DeMuth and Simon, 2009). The use of hohlraums (for indirect drive) or sabots (to protect direct drive pellets) with mass of order a gram translates to of order 1 metric ton of daily throughput, imposing demands on any storage and recycling system, including the need to treat any activated elements.
- *Mass production*—ICF targets used in research today are highly complex and expensive, requiring expert human intervention throughout the manufacture and assembly chain. For an IFE reactor, their designs need to be consistent with mass manufacture and delivery methods (~ 1 million per day per plant), and at a cost that does not preclude economic operation of the plant, which is typically $\ll \$1/\text{target}$ (Schultz, 1998; Goodin et al., 2005; Frey et al., 2007; Miles 2009).
- *Tritium inventory*—The ability to burn up a substantial fraction of the injected tritium fuel on each shot (tens of percent) is a key advantage of IFE, resulting in a reduction in overall tritium inventory in the plant. However, the target design needs to be consistent with such performance if this advantage is to be realized. Furthermore, the target manufacturing plant can account for a sizeable fraction of the onsite tritium inventory, impacting the safety stance of the facility, perhaps predicating the need for wetted foam designs rather than slow fuel filling processes such as diffusion.

Fusion fuel target injection

Inertial fusion research experiments use massive mechanical arms to hold the fuel targets at the center of the interaction chamber, and require extensive pre-shot alignment and characterization. For most approaches to an IFE plant, the fuel will need to be remotely injected in a manner that allows the pellet to arrive structurally intact at a well-defined location at a well-defined time and in the desired thermal state and orientation (if non-spherical). This imposes a number of new constraints on the target design:

- *Mechanical survival*—The target design needs to be consistent with the required acceleration in the injector without undue deformation, for example of the DT layer inside the capsule, or the position of a capsule within a hohlraum. This can be

challenging given the lack of strength of DT ice, and the need for extremely thin support membranes to avoid perturbing hohlraum-driven implosions.

- *Thermal survival*—The steady-state environment of an IFE chamber presents considerable challenges to the survival of a DT pellet, which needs to maintain its cryogenic state in the presence of radiation from the hot walls and conduction from any residual chamber gas. The pellet must preserve its spherical symmetry, surface smoothness and internal vapor pressure to a high degree of precision (Schultz et al., 2001). A principal difficulty is that the heat capacity of IFE pellets is rather small, such that less than 1 mJ of energy will heat the DT ice by more than the typical 100 mK limit. Increasing the driver energy can compensate for some level of imperfection, but this would be at considerable cost. Potential solutions have been explored, such as invoking a very low chamber pressure and low first-wall temperature (Petzoldt et al., 2002; Raffray et al., 2003) which must then be self-consistent with a chamber solution for first-wall protection. Alternatively, the use of a thermal shield can be invoked, either within the pellet, as a transient overlayer, or in a protective sabot. But any such scheme needs to be consistent with the constraints imposed by manufacturing (such as cost), injection (size and shape), target performance, and waste management constraints (activation and recycling), as is the case anyway for indirect drive targets (Miles et al., 2011). The timing of removal of any sabot or overcoat needs to be self-consistent with the in-chamber environment, with typical timescales for exposure of an unprotected pellet being < 100 ns (~1 cm of flight).
- *Tracking*—Precise timing of the driver is needed so that the target arrives at the chamber center synchronously with the driver energy. The gating event is likely to be the flight of the target, such that an in-chamber tracking system needs to be able to provide a timely trigger for the pulsed driver. The need for an active interrogation system may impose additional requirements on the target design, such as adequate reflectivity to a probe, as well as requirements on the chamber design to provide lines of sight, as well as protection of the tracking components. This may be incompatible with some approaches, such as the use of liquid sheets.
- *Placement*—The fuel needs to be placed at a location consistent with the focused energy of the driver. The absolute position may be relatively relaxed if there are active alignment systems for the driver, but the relative position tolerance (e.g., beam placement on the pellet or hohlraum) is typically very tight. Bare spherical pellets have some disadvantages with regard to their poor flight characteristics in a non-vacuum environment, and particularly in an inhomogeneous and potentially unpredictably turbulent gas. The thermalization provided by a hohlraum conceivably offers some lessening of the positional tolerance, although evidence to date is that beam placement is at least as difficult as for a spherical direct drive implosion.
- *Reliability*—The integrated target injection, tracking and ignition system needs to perform with a high degree of system reliability. Targets that do not ignite produce no energy and so degrade plant capacity factor. Targets that absorb driver energy but do not ignite can also produce high velocity debris that can damage other equipment. If ignition interruptions are sufficiently long, they can also create thermal transients that create cyclic thermal mechanical loads and challenge plant control systems.

Overall, the target survival, tracking and placement tolerances impose substantial self-consistency constraints on the overall design of the fusion chamber, driver and exhaust systems, as well as on the target design itself.

Alternative approaches that do not require injection (e.g., Z-pinch designs) impose stringent requirements on rapid, low-cost replacement of mechanical components, recycling of the irradiated byproducts, and often the need for multiple parallel interaction areas with all the associated infrastructure.

Fusion chamber

The heart of an IFE power plant is the chamber that serves to host the fusion reaction. This is a complex interdependent system in its own right that needs to: enable successful target and driver propagation to the chamber center; capture and transmit thermal power to the balance of plant; breed sufficient tritium; remove residual target debris; reset for the next pulse; and maintain sufficient longevity and availability for sustained multi-year operation. Many different conceptual approaches have been explored, and are summarized in the final section of this article. The chosen approach needs to be consistent with the other sub-systems, taking into account:

- *Chamber survival vs target survival*: A key topic that was underappreciated in some early designs of IFE chambers (Conn et al., 1977; Meier et al., 1994; Sviatoslavsky et al., 1993) was the need for self-consistency between mechanical survival of the first wall (which typically calls for a back-fill gas to range-out the problematic ions and X-rays, but not too high a pressure to induce blast wave damage) and thermal survival of the injected fuel pellet (which typically calls for as low a density as possible, particularly for direct drive approaches). Solutions have focused on the use of armor plated or nano-textured walls in very large chambers with a low-density gas, coupled to magnetic deflection of ions and aggressive exhaust systems (in designs that favor preservation of a simple pellet design); or the use of a more conventional steel wall in a smaller chamber with a higher-density gas for designs that invoke indirectly driven targets. There are also various approaches to incorporating liquid sheets (to protect the wall from X-rays, ions, and debris), for which the vapor pressure and potential presence of droplets must not interfere with the target survival, and which themselves must recover from the disruption from the target best prior to the next injection.
- *Chamber survival vs driver performance*: Similarly, any gas or liquid in the chamber needs to be consistent with high quality propagation of the driver beams (limiting the allowable gas density, heterogeneity/turbulence, and presence of droplets and condensation on optics, as well as placing constraints on the optical geometry for liquid sheet designs). Temperature stability of the optics is required in order to preserve the focusing and pointing characteristics, as is isolation of the laser systems from the

harsh neutron environment in order to enable a practical maintenance regime consistent with the overall plant availability requirements.

- *Chamber maintenance vs system integration:* Separate to the issue of first wall protection from ions and X-rays is the need for all the in-chamber components and associated structural materials to withstand the integrated neutron dose for a full maintenance cycle of the plant (which may be as short as a few years for line replaceable components, or as long as the lifetime of the power plant for structural components). The interdependencies here are with the overall concept for tritium containment and vacuum preservation in the chamber volume, likely predicated a separability of the first wall from the hermetic sealing system (Malang et al., 1998; Latkowski et al., 2011), and potential interference between periodic removal of chamber components and other sub-systems such as the final optics assemblies.
- *Chamber environment vs target design:* As noted above, the chemistry and radiochemistry of target by-products and any in-chamber gas and first wall materials needs to be self-consistent, avoiding unwanted condensation/plating; minimizing activated waste streams; ensuring an ability for timely reset to acceptable “ambient” conditions for the next pulse; and compatibility with cold-start/restart scenarios when the chamber temperature drops below its steady-state level and potentially below the freezing point of any residual chemicals.
- *Chamber design vs heat extraction system:* In the fluid-mechanics and structural design of the chamber and associated blanket/heat extraction system, there is a balance to be struck between: (i) running the thermal loop at high temperature for efficient heat extraction; (ii) the need to limit the temperature to allow use of cost-effective conventional steel piping and commercial turbines; (iii) avoidance of temperature regimes that accelerate corrosion in the primary heat exchange loop (which is a problem for liquid metals such as $\text{Li}_{17}\text{Pb}_{83}$ and salts such as FLiBe (a 2:1 eutectic mixture of LiF and BeF_2)); (iv) use of materials that provide sufficient strength at the high operating temperatures; that are resistant to neutron-induced swelling; and that can withstand the fatigue resulting from the pulsed thermal cycling inherent to IFE; and (v) choice of an efficient single heat exchange loop versus a dual loop to isolate the tritium.

Tritium system

- The inter-relationship between the chamber design, the associated breeding blanket, thermal loop, chamber exhaust, and the tritium processing and containment systems are all extensively covered elsewhere. These need to ensure there is overall tritium self-sufficiency (Abdou et al., 1986), and a safety regime consistent with regulatory and public acceptance requirements.
- In addition, there is a direct impact on target design due to the need to maintain an acceptable site inventory. There must be a sufficiently high burnup fraction ($\sim 30\%$), compatibility with rapid fill schemes (e.g., via wetted foams rather than diffusion and layering), and elimination of materials that could lead to tritium retention in the chamber (e.g. via the formation of metal hydrides with the walls, tritium implantation in the wall, binding to lithium, or formation of organic molecules via interaction with carbon from the target). Similarly, the exhaust chemistry must avoid tritium bonding into species that would compromise efficient reprocessing.

Waste stream processing system

- Every element of the plant design needs to account for its eventual disposition, and be consistent with the overall value proposition of the power plant to the owner and other stakeholders (Fetter et al., 1990). Particular consideration needs to be given to design choices that can result in day-to-day operational waste, and whether these will impose a need to store, transport and dispose of low-level nuclear waste (El-Guebaly et al., 2006). Examples are the chamber exhaust (resulting from byproducts from the target assembly, as well as any chemical and nuclear interactions with the gas and walls); byproducts from the tritium processing systems, and the fate of life-limited components from the nuclear environment that can be activated and/or tritiated (e.g., final optics, first wall panels, valve seals, etc.).

Safety and environment

- Similarly, every element of the design needs to ensure rigorous consistency with the eventual regulatory licensing requirements and corresponding accident scenarios (Reyes et al., 2001, 2016). This impacts a very broad array of facility subsystems, including: target design (e.g., due to on-site tritium inventory); chamber design (e.g., to minimize decay heat after reactor shutdown, and to limit radioisotope dispersal in the event of a fire, and if possible to mitigate the prompt gamma hazard in the event of a shield wall breach); coolant loop design (e.g., tritium permeation hazard); beam path design (e.g., to ensure sufficient shielding to minimize dose to workers); and the impact of maintenance cycles and waste stream options on onsite storage of hazardous materials.
- An important environmental design consideration for a success-based approach is to ensure the raw materials required by a worldwide fleet of fusion plants is consistent with known reserves, likely production rates, competing markets, and any geopolitical limitations. There is a well-known issue with the start-up need for tritium, but prior analyses have also shown that problematic raw materials may also include: beryllium (used in blanket designs as a neutron multiplier and/or coolant),

tantalum (used in some high temperature heat exchange designs, in power conditioning capacitors, and as a corrosion inhibitor layer when used with lithium salts), gallium (used in diode-pumped lasers), and enriched lithium (if needed for the blanket design). More parochially there would be intense constraints if materials were limited to domestic supply chains, leading to considerations of strategic reserves of key materials. Finally, the production rate of specialized components (e.g., optics, laser diodes, low activation and damage resistant steels) and the need for a suitably qualified workforce for the supply chain, plant construction, and plant operations are all nontrivial issues that can have a substantial impact on the growth rate and cost of the plants if not managed appropriately, as has been seen in other parts of the energy sector.

IFE power plant design studies

Many IFE design studies have primarily focused on the complexities of the fusion chamber. These typically assessed the choice of the chamber first wall and breeding blanket materials, chamber environment compatibility with delivering the driver energy to target, the response of the chamber to the pulsed fusion energy releases, and nuclear performance (e.g., tritium breeding, activation, radiation damage).

There have also been a number of integrated IFE studies since the 1970s that have sought to incorporate the full range of considerations for a power plant. These have typically been multi-year efforts with teams of physicists and engineers from universities, National Laboratories and private industry, including architect engineering firms with expertise in the design and construction of conventional fossil and fission electric power plants. Summaries are provided by Meier (1988), Craxton et al. (2015), Olson et al. (2005), as well as Davidson et al. (2013) for the National Academies, along with industrial perspectives from the Energy Power Research Institute (Hirsch et al., 1992; Kadak et al., 2012).

Table 1 gives key fusion chamber parameters for a sample of the major IFE power plant studies, organized by driver type. Heavy-ion-beam driven designs include Osiris (Meier et al., 1994), Prometheus-H (Waganer et al., 1994) and HYLIFE-III (Moir et al., 1994). Laser driven studies include Sombrero (Meier et al., 1994), Prometheus-L (Waganer et al., 1994) and LIFE (Dunne et al., 2011; Anklam et al., 2011; Meier et al., 2014), with the first two based on KrF lasers and LIFE based on diode-pumped solid-state lasers (DPSSL). Important work on integrated technologies for a direct-drive KrF laser plant was performed in the HAPL program (Sethian et al., 2010). Note that the Z-IFE power plant concept consists of 10 chambers, each operating at 0.1 Hz with yields of 3000 MJ, for a total plant thermal power of 3000 MWt (Olson et al., 2005). Details of the power conversion cycle were not given, so the thermal, gross electric and in-plant powers listed in the following tables were scaled from HYLIFE-II, a similar thick liquid wall chamber using FLiBe.

Table 2 summarizes the key power plant features and design parameters. Osiris and HYLIFE-II selected FLiBe as the primary coolant and tritium breeding material. The two Prometheus designs split the first wall and blanket cooling functions, using Pb for first wall cooling and high pressure He for cooling the Li₂O based tritium breeding blanket. Sombrero circulated Li₂O breeding pebbles and low pressure He through the blanket structures and then through steam generators. LIFE utilized liquid Li for tritium breeding and cooling of the chamber first wall and blanket. All these plants were sized for a nominal 1 GWe net output and all proposed conventional steam-driven power conversion cycles. Power conversion efficiencies ranged from 42–47%. The laser driven design have significantly higher recirculating power requirements due to the lower driver efficiency compared to heavy ion beams. As a result, the laser-driven plants have lower total plant gain (net electric output/total electric input) as discussed previously. Z-IFE Plants have significantly higher fusion threshold energy than for ion beam and laser-based systems, which leads to single-shot fusion yields roughly an order of magnitude higher than for the other two driver technologies. Another feature of the Z-IFE design is that it has 10 fusion chambers operating in parallel, all using the same driver. This allows each chamber to operate at a lower pulse rate, facilitating mechanical replacement of the fusion targets.

Table 1 Key fusion engine parameters.

	Year	Driver energy, MJ	Driver eff., %	Target gain	Target yield, MJ	Pulse rate, Hz	Fusion power, MW	Chamber first wall material	Chamber structural material	Breeding material
<i>Heavy ion beam driven</i>										
Osiris	1992	5.0	28.2	86.5	432	4.6	1987	C fabric	C	FLiBe

SSC	System, structure or component

Introduction

One of the main motivations for the development of fusion power for base-load electricity generation is its perceived favorable safety and environmental performance. This expectation derives from the characteristics of the fusion process, with the absence of hazardous reaction products and the strong tendency for a fusion plasma to terminate naturally in the event of any abnormality. But radiological hazards arise from the use of tritium as fuel, and from the products of activation by the high-energy neutron produced in the D-T fusion reaction (Morse, 2021; Campbell, 2021a). These hazards must be controlled and minimized.

Compared with a fission reactor, a fusion power plant will contain no actinides, no fission products, and no equivalent of reactivity excursions or core melt events. Accident scenarios are limited to events in which there is a degradation of the confinement of the radiological inventories of tritium and neutron activation products, potentially allowing some release to the environment.

Confinement of these radiological inventories must be maintained to prevent an accidental release that could pose a risk to the public, and also to prevent their spread within the plant and create an occupational hazard to personnel. Routine operation, including maintenance activities, must not result in significant gaseous or liquid effluents containing radioactive species, particularly tritium. Operation must not give rise to the accumulation of radioactive waste through replacement of components and, together with that generated at decommissioning, the waste must not become a burden on future generations.

These aims for the safety and environmental impact of a fusion power plant may be achieved by setting them as top-level objectives during the entire life cycle starting with the conceptual design, together with the adoption of safety criteria to check that they are fulfilled. One such criterion, commonly cited for fusion, is the ‘no-evacuation criterion’ that requires that there will never be the need to evacuate public from around the site, in any event no matter how unlikely. By reference to IAEA guidelines for evacuation (IAEA, 2014), this sets a quantitative limit on the consequence of any accident in terms of the biological dose expressed in units of milliSievert (mSv) (Apostolaei, 2021). The limit is 100 mSv maximum dose to the most exposed individual in 7 days (50 mSv is often assumed to provide a margin).

The safety design and operation of a fusion facility is commonly based on the application of recognized principles such as defense in depth and maintaining hazards as low as reasonably achievable (ALARA). Wherever possible, safety functions are provided by passive means, for example by employing strong static barriers that are part of the plant design (such as the vacuum vessel) to provide the confinement of radioactive materials.

In order to demonstrate that fusion can achieve its expected safety and environmental performance, safety studies of fusion have been performed to guide fusion power plant design in optimizing the safety implementation, and to ensure successful nuclear licensing for construction and operation. These include studies of conceptual designs for fusion power plants, particularly in Europe (Cook et al., 2005) and the US (Petti et al., 2006), and the extensive studies of ITER (Taylor et al., 2011) for the safety case presented to the French nuclear safety authorities in order to obtain the license to construct the facility in the south of France (Taylor et al., 2013).

Main safety and environmental concerns for fusion

Radiological hazards in a D-T fusion plant, whether magnetically or inertially confined, arise from two sources: the tritium used as fuel and generated in breeding blankets (Boccaccini, 2021), and the products of neutron activation.

Tritium hazards and their amelioration

Tritium is a pure beta-emitter with a half-life of 12.3 years. The beta particle has a low energy, averaging 5.7 keV. This particle has a range of only 6 mm in air, or typically 6 μm in organic matter. The principal radiological impact is therefore not from exposure but from inhalation, ingestion or through skin absorption. The biological hazard coefficient for ingestion of tritium is 4.2×10^{-11} Sv/Bq, some three orders of magnitude lower than that of ^{131}I . The difficulty with tritium arises from its nature as an isotope of hydrogen; it diffuses readily into and through materials, leading to retention of tritium in structures and challenges in its confinement. Furthermore, it exchanges with hydrogen in molecules such as water, creating tritiated water HTO, and also in organic matter and other hydrogen-containing material.

Significant inventories of tritium are likely to be found at many locations in a fusion power plant:

- Retained in the vacuum vessel, where it will be adsorbed onto surfaces, permeated into the structure of components inside the vessel (in-vessel components, IVCs) and absorbed into dust generated by erosion of surfaces;
- In equipment used to fuel the plasma, to pump exhaust from the plasma chamber, and to recover and process tritium from that exhaust, collectively known as the fuel cycle system;
- In breeder blankets where it is generated, together with the system to extract tritium from the blankets and to process and store it for use as fuel;
- As contamination of remote maintenance equipment used to remove components from the vessel and transport them to a maintenance facility;
- In the storage facility for in-vessel components awaiting maintenance or disposal;
- In the maintenance facility where components are treated, repaired, dismantled and prepared for disposal;
- In coolants, due to permeation through cooling channel walls;
- In the atmospheres of any rooms containing tritium-contaminated items.

The hazards presented by these inventories are three-fold: the risk of inhalation by plant personnel (i.e. occupational radiation exposure), routine effluents in gaseous or liquid form during normal operation or maintenance, and the risk of an accidental release to the environment in an off-normal situation. The approach to minimizing each of these hazards is the same: reduce tritium inventories and provide effective confinement. Minimization of inventories needs to be done at the design stage, by designing systems that can perform their function with the lowest possible quantity of tritium, avoiding features that may lead to tritium retention (including the choice of materials), and segregating tritium inventories so as to limit the maximum quantity that could be mobilized in case of a failure or degradation of confinement systems.

Confinement systems to prevent or minimize occupational radiation exposure utilize room ventilation based on nuclear-grade HVAC (Heating Ventilation and Air Conditioning) systems. These maintain a pressure cascade between adjacent rooms to ensure that air flow is always in the direction towards the more highly contaminated spaces. Conventional nuclear HVAC systems remove airborne contamination by filtering the air before it is recirculated or vented to the environment. However, they cannot remove tritium. To be able to do this, large and complex atmosphere detritiation systems are required typically based on a series of scrubber

columns. Such systems have limited maximum flow rates compared with the regular HVAC systems, for which reason flow is likely to be diverted to them only when a tritium concentration above some threshold is detected in a room.

For the minimization of routine effluents and of accidental releases, confinement systems comprise a series of strong barriers together with the same ventilation and detritiation systems. Providing the confinement function by passive means is an important objective, to reduce dependency on active safety systems. Nevertheless, the atmosphere detritiation systems mentioned above will always be necessary to reduce tritium concentration in effluent being vented to the environment. Where possible, strong barriers that are present in the design are utilized as confinement barriers, for example the vacuum vessel itself to protect the in-vessel inventory of retained tritium. Such barriers, however, may have a number of penetrations; in the case of the vacuum vessel these include cooling pipes, ducts for neutral beam systems, waveguides for RF heating systems and diagnostics, feeders for in-vessel coils, fueling and pumping systems. At each of these penetrations, seals, bellows, windows, isolation valves and parts of the ducts or pipework become part of the confinement barrier and need leak-tightness with high reliability.

Neutron activation and its consequences

14 MeV neutrons from the D-T fusion reaction (Campbell, 2021a) penetrate all structures and components around the plasma and are slowed-down through scattering reactions, resulting in a broad energy spectrum down to thermal energies, but always with a dominant peak at 14 MeV. This moderation to low energies is deliberately promoted by typical breeder blanket designs, since the major tritium-producing reaction in lithium-6, ${}^6\text{Li}(n, \alpha)\text{T}$, has its highest cross section at thermal energies.

During the transport and slowing-down of these high-energy neutrons, they take part in many reactions that cause transmutations in the materials of the plasma-facing components, and to a lesser extent the vacuum vessel and components outside of it. The high-energy part of the neutron spectrum enables many reactions with threshold energies that leave them unimportant in fission reactors, including charged-particle producing reactions such as (n,p), (n,d) and (n, α) (Wietfeldt, 2021). The outcome, for irradiation of typical stainless steel, is a material composition comprising hundreds of nuclide species. These include many radioactive nuclides which may be broadly classed into three categories according to their half-lives:

Short-lived nuclides that decay on the timescales of minutes or hours. These may provide intense gamma radiation as they decay, but only in the short term. They are of potential importance in postulated accident scenarios involving a loss of confinement; if they may be mobilized and released from the plant, they may provide radiological doses to members of the public in the vicinity of the plant.

Medium-lived nuclides with lifetimes of days or weeks. Their gamma radiation has the potential to cause occupational doses to personnel involved in maintenance activities when the plant has been shut down. To avoid such exposure, remote handling techniques will be deployed for the removal and replacement of components including their transport to the maintenance facility. The remote handling equipment must be qualified to operate in the high radiation fields.

Long-lived nuclides with half-lives of months, years or longer. These constitute a large volume of active material that must be handled and stored during final plant decommissioning and dismantling. The longer-lived nuclides will result in some of this material, together with that of components removed during operation, ultimately requiring disposal as radioactive waste.

One important approach to minimizing the impact of neutron activation is through the choice of materials in those components exposed to the neutron flux (Litnovski, 2021). Specially designed materials for fusion systems have been developed as alternatives to conventional steels (Tanigawa et al., 2017). Referred to as low-activation or reduced-activation materials, they have a composition that omits or minimizes those elements whose activation products are dominant. It is also important to restrict the levels of some impurities in steels, as these often contribute significantly to the activation. For example, cobalt, a typical impurity in stainless steel, generates ${}^{60}\text{Co}$, which has a 5.3 year half-life and emits high-energy gammas. At typical cobalt concentrations in conventional stainless steels, ${}^{60}\text{Co}$ dominates the gamma dose rate arising on the timescale from 6 months to 50 years after shutdown.

With regard to activation products providing a potential source term for release in postulated accidents, the degree to which the active material may be mobilized must be considered. Although much of the active material is stable inside solid structural or other materials, some of it may be mobilized if the accident scenario involves high temperatures. Furthermore, the plasma-facing surfaces become eroded during plasma operation generating dust that accumulates inside the vessel and may be easily mobilized in some accident scenarios. This dust is not only radioactive but may also absorb tritium.

Active dust accumulated inside the vessel, and any other mobilized activation products, require confinement by exactly the same means as those discussed above for tritium. The important difference compared with tritium is that airborne dust may be readily removed in ventilation systems by the use of high efficiency particulate-air (HEPA) filters.

Although in normal operation the products of neutron activation are well confined inside the tokamak and their radiation blocked by a biological shield, there is one significant exception. In water cooling circuits corrosion of the surface of coolant channels, pipework and components of the cooling system produce corrosion products that are carried around the cooling loop. These are largely in solution in the water, but also include some particulate matter. If the origin of the corrosion is material in active components these products are a source of gamma radiation, and material originating in any part of a cooling loop becomes active when it is carried by the coolant through the region under neutron flux. The result is an inventory of activated corrosion products (ACPs) that are transported throughout the cooling circuit, including those parts outside of the bio-shield. Some of this ACP inventory deposits on surfaces throughout the loop so that, even after the water is drained for maintenance, the pipework and components provide a significant source of gamma radiation.

Looking further into the future it is conceivable that instead of D-T fusion, an aneutronic fusion reaction could be employed, i.e. one that does not directly produce neutrons. However, reactions of this type, for example $D-^3\text{He}$, all require conditions that are more difficult to achieve, and some production of neutrons cannot be precluded due to other reactions, such as D-D, also taking place within the plasma.

Implications from safety analyses

Studies of the safety of fusion facilities are done during design activities in order ensure that the design includes all required safety provisions and that these are optimized to reduce the safety and environmental impact of operation. Safety analyses not only provide feedback to the design process, but also prepare essential information used in a safety case as part of the licensing process to authorize construction, commissioning and operation.

Safety functions and classification

It is essential to define the functions that must be provided to ensure that the facility remains in a safe state, even in off-normal conditions or with the failure or malfunction of one or more systems. For fusion, two top-level safety functions are generally defined:

- The confinement of radioactive materials;
- Limitation of exposure to ionizing radiation.

For the first of these, every inventory of tritium and activation products, as outlined in Section “**Main safety and environmental concerns for fusion**” above, must be protected by a series of strong barriers. These prevent the spread of radioactive contamination within the plant and ultimately avoid or limit the amount released to the environment in accident conditions. The second safety function is focused on protecting personnel from radiological doses, and is achieved by means of radiation shielding coupled with strict access control to hazardous areas.

To ensure that these safety functions can be provided in all plant conditions, a set of supporting functions are defined, for example the control of energies that might present a challenge to confinement barriers.

The safety functions and their supporting functions are provided by systems, structures and components (SSCs) in the plant that have a role to play in maintaining safety. Such SSCs are classed as importance to safety, and have a Safety Importance Class (SIC) assigned to them according to the consequences if they fail to provide their function. The highest level, SIC-1, is assigned to SSCs that are needed to ensure that the plant remains in a safe state, or is returned to a safe state following the initiation of an accident scenario. Lower levels, SIC-2 and sometimes SIC-3, indicate an SSC that provides mitigation of the consequences of an accident, but whose function is not essential to reach a safe state. Quantitative definitions of the SIC levels are commonly used.

The classification of SSCs as SIC implies a set of requirements for their design, manufacture, qualification and monitoring or inspection during service. It also allows their correct functioning to be credited in analyses of postulated accident sequences. If, in the course of those analyses, it is found necessary to assume that some SSC behaves in a particular way to obtain a favorable outcome, then this behavior becomes a requirement and the SSC is classified as SIC.

Accident analysis for fusion

A central part of safety analysis is the evaluation of the possible consequences of postulated accident scenarios. This is done by detailed computer modeling of the systems that could be involved, and their response to the abnormal situation. Usually, for fusion systems, this is done using deterministic accident analysis. It involves the determination of source terms, i.e. the quantities and characteristics of the radioactive inventory vulnerable for release, which typically requires neutronics and activation modeling to establish full nuclide-by-nuclide compositions. In scenarios involving the flow of coolant or other fluid, it requires thermal-hydraulic modeling. It may require aerosol modeling to represent the transport of airborne radioactive species through the plant. And it may need calculations of the effects of over-pressure on structures, including, in some cases, explosion modeling. Throughout these calculations, conservative assumptions are made to ensure that results represent the maximum consequences of the accident scenario. The outcome is an evaluation of the maximum releases of radioactive material from the plant to the environment in the given scenario, typically tritium (both elemental, T_2 and as tritiated water, HTO), neutron activated material (particularly dust), and in some cases ACPs. These are then used as source terms for the modeling of dispersion in the atmosphere, transport to locations where people may be present (e.g. the site boundary), and evaluation of the potential radiological dose to the most exposed individual.

This kind of analysis must be performed for each accident scenario for a number of postulated events, ensuring that the set of scenarios studied cover the complete range of accidents that are possible—even with very low likelihood—in the plant. To ensure that the range of events analyzed is fully comprehensive it is essential that accident identification studies are performed using systematic methods. Typically this is done with Failure Modes and Effects Analysis (FMEA), in which all conceivable failure modes in all components of the plant are listed and their potential impact on the plant assessed (Pinna et al., 1998). Failures in different components that lead to a similar impact on the plant are grouped together into Postulated Initiating Events (PIEs), which are then

used to develop event sequences, usually with the aid of event trees. For each PIE, the event sequence with the greatest possible consequence in terms of radiological release is chosen as one of accident scenarios to be the subject of full analysis as outlined above.

FMEA requires sufficient detail in the design that individual components and their failures may be assessed; at early stages in the conceptual design of a facility this may not be available. In this case a functional approach may be used, using Functional Failure Modes and Effects Analysis (FFMEA) which identifies the functions provided by elements of the systems and the consequences of the loss of these. Hazard and Operability (HAZOP) studies provide an alternative systematic approach to the identification of off-normal conditions that could initiate an accident sequence. These so-called bottom-up studies of accident sequences may be supplemented by top-down approaches using fault trees or Master Logic Diagrams, to determine all the ways in which an unwanted event (radiological release) could occur. Combining different approaches to accident identification provides greater confidence that the final list of scenarios is complete.

An alternative to the deterministic accident analysis approach outlined above is Probabilistic Safety Analysis (PSA) (Modarelli and Kim, 2021). However, PSA requires quantitative knowledge about failure rates and reliabilities of components in systems, usually derived from operational experience of similar plant. At this stage in fusion development, many key systems are novel and first-of-a-kind, so that such data is not available. For this reason, it is currently not feasible to apply PSA to fusion facilities.

As well as studying the potential consequences of faults and failures within plant equipment, the potential impact of internal hazards such as fire or flooding, and external hazards such as earthquake, extreme weather events, or aircraft crash must be evaluated. Such studies must ensure that the plant will be resistant to all such hazards and that no significant radiological consequence will result.

ITER safety analyses

The most comprehensive safety analysis yet performed for an experimental fusion facility is that performed for ITER (Taylor et al., 2011). The analysis was used as the basis of a Preliminary Safety Report that formed a key part of the safety submission to the French nuclear safety authorities in order to obtain the license to begin the construction of the facility (Taylor et al., 2013). The safety studies included all the elements outlined above in Sections “Safety functions and classification” and “Accident analysis for fusion.”

Using extensive FMEA studies of plant systems, a set of 25 “reference events” were selected as accident scenarios to be analyzed in detail. The outcome of these analyses showed that in all cases the public consequences in terms of radiological dose to the most exposed individual remained well below the limits and targets set in the project safety objectives, with the most severe event giving rise to less than 0.1 mSv dose. Further analyses were performed of hypothetical sequences, or beyond-design-basis accidents, in which additional failures were postulated. Even in the worst case scenario the maximum long-term public dose was evaluated as 4 mSv, well within objectives and below the level at which counter-measures such as evacuation would be considered.

Accident scenarios typically involve a large leak of water coolant from the system providing heat transfer from the in-vessel components. One of the most severe scenarios begins with a postulated large fracture of a coolant pipe in the room that houses the water pumps and primary heat exchangers. Taking as an example the system that cools the divertor, this failure leads to an immediate under-cooling of the divertor and rapid temperature rise due to the high heat flux impinging on the divertor surface from the plasma. Safety systems should shut down the plasma within a few seconds of the coolant abnormality being detected. Nevertheless, temperatures may continue to rise due to decay heat from the radioactive decay of activated material in the divertor structure. If this temperature rises high enough, the structure of the divertor is weakened and fails, releasing cooling water or steam into the vessel. Now the same cooling loop is breached at two locations, both inside the vessel and outside, where the initial failure occurred. Once all of the cooling water has drained from this circuit, the pipework presents a direct path from within the vessel to the heat exchanger room, thus bypassing the first confinement barrier. The coolant that has entered the vacuum vessel pressurizes it, and the pressure continues to rise as it is heated by decay heat in the plasma-facing components. This pressure can create a flow through the voided coolant pipes, carrying with it a proportion of the in-vessel inventory of tritium and active dust, as well as the ACPs in the water itself.

Such an event results in some part of the radioactive inventory being released into the room where the initial break occurred, here assumed to be the heat exchanger and pump room. The walls, floor and ceiling of this room now have to fulfill their role in the second confinement system, preventing an uncontrolled release to the environment. Instead, the contaminated atmosphere in the room is vented through the HVAC and detritiation systems, so that only a small fraction of the inventory is released in a controlled way via the elevated release point at the stack.

A potential complication of the accident scenario described above results from the use of beryllium as the plasma-facing surface in ITER. Material eroded from this surface becomes dust that is expected to accumulate at the bottom of the vessel, around the divertor. When the coolant water or steam enters the vessel in the event scenario described, it is likely to chemically react with this beryllium dust, producing hydrogen. This beryllium-steam reaction is exothermic, so that if a sufficiently high temperature is reached (around 600 °C), there is a potential for it to become self-sustaining even with no additional input of heat. The quantity of hydrogen produced in this case could be sufficient to create an explosive mixture, if an air ingress into the vessel is also postulated through the empty cooling pipe. Such an explosion, if an ignition source is available, could produce a peak pressure that challenges other parts of the first confinement barrier. To avoid this eventuality, it is necessary for the plasma shutdown system to operate before the temperature of the divertor, and thereby the beryllium dust, has reached 600 °C.

Detailed analysis of this scenario, as outlined in Section “[Accident analysis for fusion](#),” has shown that even in the worst case, the radiological release to the environment is small, and the maximum dose to a member of the public would be less than 0.1 mSv. Analysis of all other ITER reference events yielded lower maximum public doses than this worst case.

Beyond design basis accidents

The ultimate safety margin provided by a fusion power plant may be demonstrated by postulating hypothetical event sequences involving multiple independent and low-probability failures. By taking a scenario corresponding to a reference event considered within the design, and postulating the failure of safety important class components that have been credited in the analyses, a beyond design basis accident (BDBA) scenario is defined. Analyses of the consequences of such a highly unlikely event gives confidence that the outcome of the worst sequence will be acceptable, for example by not violating the no-evacuation criterion mentioned in Section “[Introduction](#)” above.

An important demonstration in the study of BDBA scenarios is the absence of “cliff-edge” effects. This means that as progressively more and more independent failures are postulated, leading to lower and lower probability of the complete event sequence, a point is not reached at which there is a sudden increase in the consequences of the accident.

The accident scenarios involving a loss of cooling, such as the sequence described above in Section “[ITER safety analyses](#),” may be aggravated by postulating additional failures. After shutdown, the only source of heat is from radioactive decay, principally in the materials of the plasma-facing components within the vacuum vessel. Although this decay heat falls rapidly, if not rejected by some cooling system it may promote temperature rises in structures that could challenge their integrity. Typically, in the event of failure of all the cooling systems of in-vessel components, the cooling system of the vacuum vessel has adequate capacity to remove the decay heat and prevent damaging temperature rises. Only a small flow rate in the vacuum vessel cooling circuit is required to remove this decay heat, so that separate emergency pumps that can be powered by diesel generators provides protection against loss of electric power and other failures.

An example of a BDBA scenario related to this loss-of-cooling event is to postulate that even this emergency cooling system of the vacuum vessel fails, so that there is now no active cooling system operating in any part of the tokamak. Heat transfer away from the hot in-vessel components is then only by passive conduction and radiation, towards the cooler components (including cryogenic superconducting magnets) outside the vessel. Passive heat transfer across the volume of the cryostat is very limited, as it is designed, in normal operation, to provide good thermal insulation of the magnets and features thermal shields with low emissivity. Analyses of this BDBA event for ITER have shown that filling the cryostat with some gas, such as air or helium, provides a convective heat transfer path that results in adequate rejection of decay heat and avoids excessive temperatures in in-vessel components. Because of the large thermal masses involved and the only modest level of decay heat, temperatures rise only slowly, meaning that the action of allowing air (or helium) into the cryostat is not urgently required, but may be initiated on the timescale of days or even weeks after the onset of the accident.

Licensing and regulations for fusion

Although there have been many experimental tokamak and other fusion devices, only two have so far used both tritium and deuterium as fuel and have achieved D-T fusion reactions. These are TFTR at the Princeton Plasma Physics Laboratory in the USA, which completed operations in 1997, and JET the European tokamak located at the Culham Science Centre in the UK. Only limited tritium inventories were used at TFTR and JET, and a restricted number of D-T neutrons generated, so that neither required licensing as a nuclear facility. Many other tokamaks have used deuterium fuel and generated neutrons via D-D fusion, but none at a level significant enough to warrant nuclear licensing. When considering the licensing of future fusion power plants and the regulations that may apply, it is useful to look at nuclear licensing in an international context and consider the principles that are common in the approach of different countries ([Williams, 2021](#)).

The construction of ITER is the first project requiring nuclear licensing of a fusion facility ([Taylor et al., 2013](#)). At its site at Cadarache in the south of France it is subject to the same regulations as any other nuclear facility in France, and its construction, commissioning, operation and decommissioning require authorization by the French nuclear safety authority (Autorité de Sûreté Nucléaire, ASN). Any facility in France categorized as a basic nuclear installation (Installation Nucléaire de Base, INB) is regulated by the same law, the *loi no. 2006–686 relative aux installations nucléaires de base et au contrôle, en matière de sûreté nucléaire, du transport de substances radioactives*, known as the TSN law (for Transparency in Nuclear Safety). ITER is categorized as an INB because of its expected significant on-site tritium inventory.

Whereas in France all nuclear facilities, from power reactors to fuel stores, research laboratories and accelerators, fall under the same law and new nuclear fusion plant are readily included in the scope, in many countries the existing nuclear legislation is more limited in scope. In such cases existing laws and regulations are typically focused on fission power plant, and new fusion facilities do not fall within their scope. It will then be necessary to enact new laws and regulations specifically to authorize the construction and operation of a fusion plant. In the development of such fusion-specific regulation, two important principles are that regulations should be *targeted* and *proportionate*. This means that the requirements arising from regulations developed for fusion should be concomitant with the nature and level of hazards presented by fusion facilities. This may lead to a simpler licensing process

than an approach in which attempts are made to adapt existing nuclear fission regulations to fusion plant. For example, the absence of reactivity accidents and of core melt events removes some of the safety provisions required in a power plant.

Another important absence in a fusion power plant is that of actinides. There is no requirement for any fissile or fertile material in the facility, which may significantly simplify requirements for nuclear security. Although tritium has its application in nuclear weapons technology, it is not currently a safeguarded material and is not subject to any provision in the Non-Proliferation Treaty or related agreements. It is however subject to export control provisions in some countries, not only tritium itself but also tritium technologies. As there will be significant quantities of tritium (order of hundreds of grams) stored, processed, burnt and generated in the systems of a fusion facility, a very strict tritium accountancy system will need to be established to guard against the diversion of small quantities for clandestine use.

The other area of possible proliferation concern for a fusion plant is in the potential use of neutrons from fusion to breed fissile material that could be used for weapons. Introducing fertile material such as ^{238}U into a blanket would result in the generation of ^{239}Pu , for example. As noted above, however, no fissile or fertile material is legitimately present in a fusion plant. Thus applying safeguards is straightforward, requiring only the verification that no fertile material is present on site. This contrasts with a fission reactor where a fine balance of large inventories of fissile and fertile material on the site, or entering and leaving it, must be maintained. The legal framework for this is the Non-Proliferation Treaty and an Additional Protocol signed by many states that allows for the verification of the absence of nuclear material. The technology to detect fertile material is readily available and may need to be applied to verifying fresh blanket materials that arrive on the site.

Additional considerations for fusion-fission hybrids

A combined fusion-fission power plant concept may be conceived to comprise a D-T fusion plasma, typically in a tokamak configuration, surrounded by a sub-critical fissile blanket that provides energy multiplication using the 14 MeV D-T neutrons. The enhanced neutron population could provide adequate breeding of tritium fuel as well as conversion of fertile material into fissile, or other transmutation of actinides.

The presence of fusion and fission technologies in a single plant would lead to a combination of hazards requiring additional safety provisions. The attractiveness of a pure fusion system, with the absence of actinides, fission products and potential reactivity accidents, is diminished. Confinement systems have to be designed not only to protect inventories of tritium and activation products, but also actinides and fission products. Accident scenarios that may challenge confinement systems will include those arising from additional initiating events and with additional consequences of, for example, loss of cooling functions. The spectrum of radioactive material that could be released now includes a substantially wider range of nuclides.

The replacement of in-vessel components of a fusion plant, first wall, blankets and divertors, is the most challenging maintenance operation of the plant and introduces additional risks that must be mitigated by specific additional confinement and shielding provisions. In a fusion/fission hybrid plant the difficulty and complexity is augmented by the need to replace fission fuel assemblies in an operation similar to that of refueling a fission reactor.

Finally, the simple approach to avoiding proliferation concerns in a fusion facility, by requiring no fertile or fissile material on site, is also lost. A fusion/fission hybrid plant would be subject to the same safeguards procedures as any fission reactor, but with the additional concern of a significant inventory of tritium.

Management of radioactive waste from fusion

The quantity of material in a fusion facility that experiences a neutron flux is potentially quite large. The in-vessel components (i.e. the first wall, blankets and divertor) experience a high level and accumulate significant neutron activation, and the vacuum vessel and some components outside of it are also irradiated by neutrons with sufficient fluence to become active at a level too high to allow direct handling by human intervention, at least at early times after shutdown. The ex-vessel components that may become active include supporting structures of toroidal field coils, other structures and shields inside the cryostat, and the cryostat vessel itself. Parts of the bioshield, in performing its function of absorbing neutrons that have penetrated the various components providing shielding, will also acquire some level of activation.

There may therefore be a large volume of active material arising from decommissioning at the end of plant life, augmented by those in-vessel components that have been removed from the plant to be replaced during the operational life. The majority of this material is at a low level of activation and would be categorized as low level or very low level waste. Components that have been irradiated in the high neutron flux inside the vessel can be expected to be categorized as intermediate level waste. No high-level waste is foreseen from a fusion plant. Much of the material decays with a relatively short half-life, so that storage for some tens of years before disposal may allow a more favorable waste categorization.

To minimize the quantity and level of radioactive waste, the use of reduced-activation or low-activation steels, particularly for the structure of in-vessel components such as the blankets, is commonly proposed. The minimization of some impurities in materials compositions can be important, as some have activation products that contribute significantly on the longer timescale. An important example is cobalt, in which the reaction $^{59}\text{Co}(n, \gamma)^{60}\text{Co}$ generates the high-energy gamma emitter ^{60}Co , with a 5.3 year half-life. This nuclide typically dominates gamma dose rates on the timescale of relevance to maintenance and decommissioning operations,

up to 50 years after shutdown. At ITER, although in-vessel components are fabricated from 316L(N) stainless steel, the specification for an ITER Grade of this steel limits the cobalt content to 0.05% by weight, compared with the 0.2% more common in standard steels.

For ITER, a detailed characterization of radioactive waste has been carried out (Rosanvallon et al., 2016), according to the waste classification scheme employed in French regulations. The in-vessel components become classified as intermediate-level long-lived waste (Moyenne Activité à Vie Longue, MAVL), the vacuum vessel as low/intermediate-level short-lived (Faible et Moyenne Activité à Vie Courte, FMA-VC), and most of the ex-vessel structures within the cryostat as very low-level waste (Très Faible Activité, TFA). There is no material qualifying as high-level waste (Haute Activité à Vie Longue, HAVL). At decommissioning, the total quantity of TFA may exceed 20,000 tonnes, FMA-VC around 13,000 tonnes and MAVL 2500 tonnes.

Those components that have been in-vessel will be not only activated by neutrons but also contaminated with tritium, both on the surfaces and by permeation into the bulk of the material. The expected level of tritium contamination may initially exceed the level at which this MAVL material could be accepted into an existing waste repository in France, so it is planned to store the material in an interim storage facility for some tens of years to allow for some tritium decay (Decanis et al., 2016). Other techniques for the detritiation of solid wastes have been studied as it may be necessary for future fusion facilities such as DEMO (Taylor et al., 2019). These techniques generally involved bulk heating, baking or even melting of the material to release the tritium permeated into the bulk.

As well as material that will become activated, there are components of the fuel cycle systems that have no exposure to neutrons, but will be treated as radioactive waste purely because of their contamination with tritium.

For DEMO and future fusion power stations (Campbell, 2021b), the quantities of radioactive waste could be higher than in ITER. The potentially increased level of activation due to higher neutron fluence levels will be offset by the use of low-activation materials such as specially developed ferritic-martensitic steels. It has long been the aim of conceptual power plant studies that the amount of waste requiring permanent repository disposal may be minimized by applying the principles of clearance and recycling (Zucchetti et al., 2001). Clearance allows material that has fallen below defined radioactivity levels to be released from regulatory control and re-used for any purpose, for example by applying the criteria defined by the IAEA (2014). Recycling of material that does not meet this criterion may still be possible in applications where a level of residual activity would not preclude its use, for example within future nuclear facilities.

An illustration of the decay of the activation products in waste material is provided in Fig. 1. This shows how the total beta and gamma-ray activity in the steel structural material of an in-vessel component decays during the 1000 years after shutdown of the plant. This is from analysis of a proposed breeder blanket design for a European DEMO reactor (Gilbert et al., 2018), which uses Eurofer, a reduced-activation ferritic-martensitic steel, as its structure. Also plotted are the contributions of the dominant nuclides. It is clear that, apart from ^{55}Fe , most of the long-lived activity comes from neutron activation of impurities and trace elements in the steel composition. Also indicated is the limit below which the material would be classified as Low Level Waste (LLW) according to regulations in the United Kingdom. It is clear that only ^{14}C , which is generated by the $^{14}\text{N}(n,p)^{14}\text{C}$ reaction, prevents the material from becoming LLW after around 100 years of storage. Nitrogen is included in the steel composition at typically 70 ppm to increase strength and resistance to corrosion (Litnovski, 2021). Removal of ^{14}C , which has a half-life of 5700 years, would therefore be beneficial, and this may be possible during smelting of the material for casting into ingot form for storage or recycling (Di Pace et al., 2019), at which stage tritium could also be removed.

Fig. 1 Evolution of beta and gamma activity in steel structure of a DEMO breeder blanket following shutdown of the plant.

In addition to the large quantity of solid radioactive material, albeit most of it at a low or very low level of activity, there is likely to be some liquid waste stream from the plant, as well as routine gaseous effluent as mentioned in Section “**Tritium hazards and their amelioration.**” The liquid waste will mainly be fluids into which tritium has permeated, as well as coolants containing activated corrosion products. Tritium will be recovered from this waste stream to the maximum extent possible and returned to the fuel cycle. Detritiated waste water may be discharged from the plant if the activity level is below permitted levels.

University of California at Berkeley
gehud@nuc.berkeley.edu

Professor Greenspan (Ph.D., 1966, in Nuclear Science and Engineering from Cornell University, Ithaca, N.Y., USA) retired from the Department of Nuclear Engineering of the University of California at Berkeley (UCB) in 2014 but served as a Professor in the UCB Graduate School until 2019. He has nearly 60 years of nuclear energy related research experience starting in 1961 as an M.Sc. student at the Department of Nuclear Engineering of the Israel Institute of Technology. His research spans a wide range of nuclear engineering related disciplines including: theoretical and experimental reactor physics; computational methods development including development of new optimization methods for determining the minimum critical mass and for finding optimal design of radiation shields, fusion reactor blankets and medical installations; conception and analysis of advanced fusion fuel cycles and of fusion-fission hybrid reactors; as well as advanced fission reactors and nuclear fuel-cycle conception, design and analysis. The latter activity was the focus of his research during the last twenty-five years. The thrust of this

research is improving sustainability of nuclear energy along with improving economics, safety, and proliferation resistance. He has been the Principal Investigator on studies of dozens of advanced nuclear systems, including those corresponding to Generation-IV reactors and to Small Modular Reactors (SMRs). He was one of the early advocates of SMRs and led a multi-institutional international team that developed a preliminary conceptual design of the Encapsulated Nuclear Heat Source (ENHS)—an innovative nuclear battery-type SMR that is free of pumps, pipes and valves in the primary reactor system. The advanced reactor technologies addressed in his research include: heavy water reactors, pressurized and boiling water reactors, prismatic and pebble-bed liquid-salt cooled reactors, molten-salt reactors, sodium and lead-alloy cooled fast reactors, breed-and-burn reactors, heat-pipe reactors as well as fusion-fission hybrid reactors and accelerator driven nuclear reactors. His research is documented in over 400 refereed publications, over 200 non-refereed publications, 5 book chapters, and a number of patents.

Introduction

From the beginning of the Universe through to the present day, nuclear energy, nuclear reactions, and nuclear radiations have played major roles in the evolution and shaping of our universe and planet Earth. All the chemical elements we find on Earth were produced by nuclear processes in the Universe. Planet Earth is continuously exposed to nuclear radiation from primordial radioactive isotopes produced in cosmological processes that followed the Big Bang. A number of primordial radioactive isotopes are still among the Earth's constituents, including thorium ^{232}Th , the uranium isotopes ^{235}U and ^{238}U as well as potassium ^{40}K . The spontaneous radioactive decay of the nuclides of these isotopes releases nuclear energy that provides a major contribution to the heat balance of planet Earth. The internal heat source is responsible for keeping the outer core of the Earth in a molten magma state and played a major role in the geologic evolution of the Earth's continents and oceans. The primordial radiation and Earth's heat source may have also contributed to the creation as well as evolution of life on Earth. Since its birth, the Earth has been also constantly bombarded by galactic cosmic nuclear radiation, which primarily consists of protons (hydrogen nuclei) and alpha particles (helium nuclei). Hence, mankind as well as any organism on Earth, were and are being continuously exposed to background nuclear radiation throughout their evolution. The background radiation level as well as the radioactive heat source due to the decay of the primordial radioactive isotopes were significantly higher at the time of Earth formation and are slowly decreasing with time.

It is only within the last hundred and twenty years or so that mankind discovered the structure of the atom and its nucleus and learned how to harness the enormous energy potential contained within the nucleus as well as the different types of radiation nuclei and atoms can emit. Nuclear radiation was discovered in 1896, when Henry Becquerel and Marie Curie discovered that salts of uranium emitted radiation that could be detected with photographic plates. In the 125 years since this discovery, mankind deciphered the structure of the atom and its nucleus, learned how to produce artificial radioactive isotopes (Irène Joliot-Curie and Frédéric Joliot in 1934), discovered how to fission certain heavy isotopes (Otto Hahn, Fritz Strassmann, Lise Meitner and Robert Frisch, 1938/39) and learned how to establish a fission chain reaction (Leo Szilard, Enrico Fermi et al., 1942) and developed numerous applications of nuclear radiation and nuclear energy. The feasibility of releasing nuclear energy by fusing nuclei of light isotopes was postulated already in 1920 (Arthur Eddington) who speculated that such nuclear reactions provide the enormous energy released in the sun and stars. Although research of harnessing nuclear fusion for controlled generation of nuclear energy is being pursued since the late 1940s, mankind has not yet succeeded in producing sufficiently more energy from fusion reactions than the energy invested in inducing these reactions. Additional information on the history and fundamentals of harnessing nuclear energy can be found in (Norman, 2021).

Encyclopedia scope

The Encyclopedia of Nuclear Energy (The Encyclopedia) provides a comprehensive authoritative coverage of a wide range of topics related to the generation, utilization and safe handling of nuclear energy, nuclear radiation and associated technologies, for the benefit of mankind and planet Earth. It covers past developments, the present status, and research and development of advanced innovative technologies that may enable improvements in the generation and utilization of nuclear energy (including nuclear radiation). The Encyclopedia consists of 272 thematic articles written by experts and arranged in 13 Sections; each Section covers the subject area identified in Table 1.

The fundamental concept of this encyclopedia is to provide all this vast and very diversified information in convenient to read cross-referenced articles within a single publication. Each article provides an effective solid foundation of its topic and references for readers interested in deeper exploration of the subject matter.

Table 1 Encyclopedia sections, number of articles per section and the section editors.

Sec. #	Section title (# of articles)	Section editor	Section editor affiliation
1	Fundamentals and history of development of nuclear energy (17)	Eric B. Norman	Professor in the Graduate School, Nuclear Engineering Department, University of California at Berkeley
2	Commercial nuclear power reactors and their design (22)	Russell E. Stachowski	Chief Consulting Engineer, Global Nuclear Fuel

Intended readership

The articles are written at a level that users, with a bachelor degree in engineering, scientific and medical disciplines, especially in nuclear engineering, will find understandable and helpful. The Encyclopedia is intended to be an invaluable resource for students and will make an important contribution to the preservation of the vast amount of knowhow developed since the dawn of the nuclear era in the nuclear energy related fields and to its transfer to the new generation.

The Encyclopedia will also be very useful to industry and academia researchers and practitioners in the many scientific and engineering fields related to the generation and use of nuclear energy, including nuclear radiation. It will enable researchers and practitioners to refresh their memory in their field of specialization or expand their knowhow on less familiar subject areas.

The Encyclopedia will also be useful to members of the public with education in engineering or sciences who are interested in learning about specific nuclear energy or nuclear radiation related topics without having to struggle with textbooks or journal articles.

On the need for this Encyclopedia

The publication of this Encyclopedia is very timely for a number of reasons, including the following:

- Nuclear energy can play a very important role in drastically reducing the amount of fossil fuels burned for generation of electricity and, hence, the amount of greenhouse gas (GHG; primarily CO₂) emissions while, at the same time, making more electricity available for developing countries and for supporting the expected growth in the world population. Moreover, nuclear energy can make an important contribution to drastically reducing the amount of GHG emission from the transportation, industrial, residential and agricultural sectors of the economy. Hence, nuclear energy can make a vital contribution to meet the goal set by the 2015 Paris Agreement on climate change and ratified by many nations—to limit global warming to well below 2, preferably to 1.5 degrees Celsius, compared to pre-industrial levels. This point is elaborated upon below in the section: “On the Importance of Nuclear Energy in Avoiding Climate Change Catastrophe”. The state of the art in nuclear energy generation is covered in (Stachowski, 2021; Crawford, 2021).

- The Generation IV (GEN-IV) International Forum (GIF) was created in 2001 as a co-operative international endeavor of research, development, demonstration and deployment of advanced fourth generation innovative nuclear reactors that, hopefully, will be available for commercial deployment by 2030. The objectives of the innovative GEN-IV nuclear energy systems include improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection. This encyclopedia provides an update on the state of the GEN-IV R&D efforts and explains the benefits the innovative GEN-IV reactors may provide. The Encyclopedia also describes (Stanculescu, 2021) the advanced nuclear fuel cycles that offer highly improved resource utilization, greatly reduced nuclear waste, and reduced proliferation risks.
- Over the past decade or so, there has been a surge in the number of private companies, mostly supported by venture capital, that are developing advanced innovative Small Modular Reactors (SMRs); reactors designed to generate between 10 to 300 MW of electricity per unit (Stanculescu, 2021). The SMRs offer a new paradigm in the generation and delivery of nuclear power; they promise to improve all aspects of design, engineering, construction and operation of commercial nuclear power plants, including enhanced safety performance, better economic affordability, and reduced financial risk. The components (modules) of SMRs are to be of a standard design, shop fabricated in assembly lines subjected to high quality control, and then transported as complete modules to the power plant site for rapid installation. The SMRs also offer flexible power generation for a wider range of users and applications—central power stations can consist of multiple units installed at a rate that best matches the growth in power demand; alternatively, a single SMR unit can be installed in the vicinity of the power customer using a so-called distributed (localized) power grid. It is even being proposed that the hundreds of shuttered coal power plant sites could be repurposed for SMRs. This encyclopedia describes (Stanculescu, 2021) a sample of the SMRs under development and explains the incentives for their development and the benefits they offer. The Encyclopedia also describes the motivation for, and examples of, so called “microreactors”—reactors producing an electrical power of less than 10 MW. Such reactors are primarily intended for deployment in remote areas which are not connected to the grid and to which the transport of fossil fuel is very expensive, as well as to provide reliable power to sensitive installations even in case of failure of the central power grid.
- The very ambitious space explorations being planned by leading industrial countries cannot succeed without nuclear energy. Space Fission Power (SFP) systems offer the potential to enable truly ambitious exploration of outer space, and ultimately a permanent human presence in space. Most of the benefits of SFP is tied to the very high amount of energy that can be extracted per unit weight of fissile material, which can allow high powers and/or long lifetime at a relatively low mass. SFP systems also offer great flexibility in terms of being able to operate in diverse environments, including environments with no or limited solar radiation, and the ability to provide abundant electrical power and heat from kilowatts to megawatts. Applications of SFP include propulsion and/or power for spaceships, electricity and heat for exploration rovers for landing on Mars (other planets and moons) or for human colonies on the Moon or Mars. This encyclopedia describes (Poston, 2021; Bennett, 2021) the many benefits nuclear energy offers to space exploration and the many challenges that need to be overcome.
- Controlled thermonuclear fusion is the focus of major international research programs that aim to demonstrate the scientific and technological feasibility of large-scale generation of nuclear energy by the fusion of light atomic nuclei. The widely distributed fusion fuel resources together with the favorable anticipated safety and environmental characteristics of future fusion power plants provide a significant motivation for the continued development of the challenging science and technology towards the exploitation of fusion energy for the benefit of mankind. In addition to the description of the fundamental elements of the fusion process and of the principal approaches to the controlled and sustained generation of fusion energy being pursued, this Encyclopedia presents the state-of-the-art for fusion research and development and the progress towards commercial fusion energy generation (Campbell, 2021). The advantages and challenges of nuclear fusion as an energy source are summarized.
- This encyclopedia also describes the many ways nuclear radiation can be harnessed to provide enormous benefits in the fields of medicine, agriculture, modern industry, environmental protection, and public safety (Waltar, 2021). Described in the Encyclopedia are more than a dozen unique properties of radiation technology that allow for these benefits to be achieved. Even though enormous and widespread, the benefits to society from these technologies are largely unknown and unappreciated. The global markets for these technologies exceed USA \$500 billion annually and are growing rapidly.
- Also provided in this Encyclopedia is information on dozens of research reactors (O’Kelly, 2021) that are operating or under construction around the world and provide unique research capability for scientists pursuing advanced research in physics, chemistry, biology, material and other sciences. Another invaluable utilization of research reactors is the production of special radioactive isotopes for numerous applications in medical, industrial and agricultural applications, and scientific research. Some research reactors are also used for demonstrating the performance of evolutionary as well as advanced nuclear fuels and of advanced nuclear power reactor components.
- Public perception of nuclear energy varies from country to country. It tends to be most negative in wealthy democracies like Germany, Australia, and Japan. Contributing to the negative perception is a fear of reactor accidents, a fear of nuclear radiation, a fear of long-lived radioactive waste, and a fear of the nuclear technology misuse for weapons proliferation. The encyclopedia addresses these concerns and provides authoritative objective information that, hopefully, will contribute to dispelling the public misconceptions (Kadak, 2021).
- The Encyclopedia describes measures implemented to ensure the health and safety of the public from nuclear power (Rempe, 2021). These measures evolved as new lessons were learned from operating experience and unplanned events, in particular events with core damage and radionuclide release (including in Three Mile Island, Chernobyl, and Fukushima). Clearly, the

experience gained from the design, evaluation, operation, decommissioning, and regulation of nuclear power plants has led to significant safety improvements. Future advanced reactor designs are expected to incorporate innovative inherent safety features (Stanculescu, 2021).

- The encyclopedia provides a detailed description of the biological effects of nuclear radiation, of how we reliably measure radiation levels and ensure that they do not exceed the permissible levels (Miller, 2021). The Encyclopedia describes the theory and practice of radiation protection that provide the basis for regulatory requirements that are essential for the safe and beneficial use of the many advanced technologies that involve exposure to nuclear radiation. The Encyclopedia explains that everyone is exposed to natural background radiation on a daily basis; that radiation is routinely in use for diagnostics of health conditions, such as for dental and medical X-rays, and that this is the largest source of radiation exposure for almost all human population in developed countries and that the benefits from these practices far exceed their risk. The regulatory permissible level of nuclear radiation is harmless much like a moderate exposure to sunshine is harmless (and may even be beneficial, whereas over-exposure can cause sunburns). In other words, the regulatory limits of doses induced by exposure to nuclear radiation are already substantively protective, and there is no evidence of health improvements by reducing the doses below these limits. Insisting to reduce radiation exposure to as low as possible below the regulatory limits may result in harm.
- Also provided in this Encyclopedia is detailed information about the nuclear waste and how it can be disposed of safely (Poinssot, 2021; Kadak, 2021). Using advanced fuel cycles (Stanculescu, 2021; Poinssot, 2021) the amount and activity of the long-lived nuclear waste can be reduced to few percent of the amount that needs to be disposed of per unit of energy generated using the contemporary “once-through” fuel cycle.

On the importance of nuclear energy in avoiding climate change catastrophe

The world’s population is expected to grow from current ~6.7 billion people to over 9 billion by 2050. As recognized in the United Nations Resolution 70/1 “Transforming our world: the 2030 Agenda for Sustainable Development” (Stanculescu, 2021; United Nations, 2015), providing “universal access to affordable, reliable and sustainable energy” and in particular to reliable electrical energy, is central to human development, social stability and even world peace. Currently, about 2.8 billion people are still lacking modern energy services (International Energy Agency, 2017), and more than one billion do not have access to electricity. Not only the growth of worldwide population, but also the economic growth in developing countries will lead to a continuing increase in the demand for energy.

The tremendous increase in energy generation required for the benefit of the global population has to be accomplished while reducing the rate of GHG (primarily CO₂) emission. Already, “human activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels” according to the Intergovernmental Panel on Climate Change (IPCC, 2018). In order to limit the global temperature increase to around 1.5 °C, total CO₂ emissions need to be reduced to net zero by around 2050.

Germany, for example, had decided to achieve this goal by installing renewable energy generators made of solar photovoltaic panels and wind turbines. Germany also decided to close down its nuclear power plants. As a result, according to Goldstein et al. (2019), “Germany, which went all-in for renewables, has seen little reduction in carbon emissions, and, according to our calculations, at Germany’s rate of adding clean energy relative to gross domestic product, it would take the world more than a century to decarbonize, even if the country wasn’t also retiring nuclear plants early. A few lucky countries with abundant hydroelectricity, like Norway and New Zealand, have decarbonized their electric grids, but their success cannot be scaled up elsewhere; the world’s best hydro sites are already dammed.”

Goldstein et al. (2019) are also saying “we actually have proven models for rapid decarbonization with economic and energy growth: France and Sweden. They decarbonized their grids decades ago and now emit less than a tenth of the world average of carbon dioxide per kilowatt-hour. They remain among the world’s most pleasant places to live and enjoy much cheaper electricity than Germany to boot. They did this with nuclear power. And they did it fast, taking advantage of nuclear power’s intense concentration of energy per unit weight of fuel. France replaced almost all of its fossil-fueled electricity with nuclear power nationwide in just 15 years; Sweden, in about 20 years. In fact, most of the fastest additions of clean electricity historically are countries rolling out nuclear power.”

In the words of World Nuclear Association Director General Agneta Rising in 2019 (Bisconti, 2021): “The 445 nuclear reactors in 30 countries are the low-carbon backbone of electricity systems, operating in the background, day in day out, often out of sight and out of mind, capable of generating an immense amount of clean power. They are the silent giants upon which we rely today.” Table 2 lists the fraction of electricity generated during 2018 in selected countries and globally from energy sources that do not emit greenhouse gases (Pioro et al., 2021). According to Poinssot and Bourg (2021), nuclear energy is within the top three of the most environmental-friendly energy sources; in the same range as hydropower and wind-power. Measured by CO₂ emissions, nuclear energy is even the most environmentally friendly energy source.

It is being suggested (Conca, 2021) that recent research has revealed the potential for extracting practically unlimited supplies of uranium from the oceans at a cost that may come close to that of land mining. If successful, this may make fission nuclear energy practically as renewable as wind and solar (Conca, 2021).

It is not sufficient to decarbonize the electricity generation sector. In the U.S., for example, 33% of CO₂ emissions are attributed to energy generated to support the electricity sector but an additional 36% of emissions result from transportation and 19% result

Fig. 2 Conceptualized coordination of energy generation sources and demand to maximize flexibility and economic performance while ensuring grid reliability and resilience.

Most energy experts around the world are advocating the development of a portfolio of low-carbon multi-energy technologies including, in addition to hydro-power plants (with very limited potential for expansion in capacity) and the currently favored “renewable” electricity generators, nuclear power plants. Because the power output of the renewable generators greatly fluctuates over the day and over the year, these generators need to be supplemented by effective energy storage devices that significantly add to the cost of energy.

Nuclear power plants, on the other hand, can generate power at a constant rate throughout the day and the year (excluding a shutdown period of ~1 month for refueling and maintenance once every 18–24 months), practically independent of weather conditions, while requiring a smaller land area per unit energy generated relative to the area required by renewable energy generators.

Moreover, nuclear energy can be generated in the form of high temperature heat (Stanculescu, 2021; Bragg-Sitton and Boardman, 2021) that is the most economical form of energy to store and to use as a backup for the intermittent nature of the renewable energy generators. Therefore, a suitable mix of nuclear and renewables is likely to be the optimal strategy for carbon-free energy generation.

Fig. 1 (Bragg-Sitton and Boardman, 2021) is a simplified illustration of the evolving perception of integrated energy systems using contemporary nuclear power reactors (primarily Light Water Reactors, LWR) in combination with solar and wind renewable energy generators to provide electricity and heat energy for transportation and many industries including non-grid energy users.

Fig. 2 (Bragg-Sitton et al., 2021) is a simplified conceptual perception of the proposed transition away from the use of contemporary large central nuclear power plants from their traditional electricity-only production mode to their exploitation for the provision of a variety of outputs. Future energy systems that seek to maximize energy utilization, generator profitability, and grid reliability and resilience must necessarily consider all available carbon-free energy sources, using each available resource in a way that maximizes its benefits while minimizing less-desirable attributes. The future energy systems should include advanced nuclear reactors including Gen-IV reactors, SMRs and even microreactors and should use distributed in addition to centralized electricity grids.

In summary, the need to meet the objective of zero net CO₂ emission by 2050 combined with the need to greatly increase the total global energy generation rate is an enormous challenge that can be achieved only by making use of all available clean energy generation technologies including nuclear in addition to solar and wind electricity generators. At the 2021 Earth Day climate summit, U.S. president Biden called (WSJ, 2021) for slashing U.S. greenhouse gas emissions by 2030 by 50%–52% compared with the baseline year of 2005, as he seeks to put America at the forefront of world-wide efforts to combat climate change. According to WSJ (2021), meeting this objective would require dramatically reshaping key sectors of the economy, from energy to transportation to agriculture.

Concluding remarks

This Encyclopedia of Nuclear Energy provides a very comprehensive, up-to-date and authoritative information related to nuclear energy, including nuclear radiation—from the discovery of the structure of the atom and its nucleus; through the discovery of three different ways to extract energy from nuclei (fission of heavy nuclei, fusion of light nuclei and radioactive decay); through the state-of-art of the nuclear industry for energy generation and for exploitation of several nuclear technologies for medical, industrial, agricultural and other applications; to the research and development of innovative nuclear technologies that are expected to further

increase mankind benefits from nuclear energy. The reader can find in the Encyclopedia a wide range of topics ranging from the contribution of nuclear energy to the evolution of the continents and oceans of planet Earth to the enabling of very ambitious space explorations including the provision of electricity and heat to human colonies on the Moon, Mars and beyond. The Encyclopedia explains why it is essential to greatly increase the nuclear energy generation rate in order to prevent a global warming catastrophe and, at the same time, provide sufficient energy to the growing world population and to the billions of people in underdeveloped countries.

It is hoped that this Encyclopedia will make an important contribution to transferring of the huge amount of technical knowledge accumulated in the field to the young generation, will inspire students to join research and development of innovative nuclear technologies and will contribute to better understanding of the nuclear technologies, their merits and safety by the general public and policy makers. The appreciation of the enormous benefits in the fields of steady reliable clean energy generation, medicine, agriculture, modern industry, environmental protection, and public safety that mankind enjoys every day and which is described in this Encyclopedia will, hopefully, contribute to much greater public acceptance and support of enhanced utilization of nuclear energy in the mix of clean energy technologies.

Acknowledgments

The Editor-in-Chief is very thankful to the Editors of the 13 sections of this encyclopedia who worked very hard and with dedication to compose the scope of their sections, find expert authors for each of their section articles and finally review and revise these articles. Many thanks are also due to the several hundred authors of the encyclopedia articles who agreed to share their expert know-how with the readers. The support provided by the Encyclopedia Content Project Manager Natalie Lovell, by the Associate Content Project Manager, Gayathri S and their staff is highly appreciated.
